So long as the parts of the ear concerned in sound transmission remain in a normal state, sound may be said to almost exclusively reach the auditory nerve by means of their action, and since impulses of sound are thus practically excluded from all other channels (tissues) of transmission, the confusion which would otherwise arise is avoided.

Disease, however, may give rise to changes in the transmitting mechanism, owing to which vibratory impulses are but imperfectly conveyed in the natural way, *i.e.*, by aerial conduction, and then it is that the auditory nerve takes cognizance of sounds hitherto excluded from it by the peculiar arrangement of the transmitting apparatus; these unpleasant and strangely sounding undulatory vibrations are received through the osseous, muscular, and other tissues.

This altogether anomalous hearing, which may exist for a time continuously, or may be interrupted, as it were, by almost normal hearing, is dependent for the most part on the passage of sound to the ear through both aerial and tissue media at the same moment. Owing to the increased intensity of sound, thus partly heard coming through the better conducting medium of the tissues, an extremely confusing and disagreeable effect is produced, and the definition of an exclusively aerial transmission is wanting.

As is well known to otologists, hearing may thus become a very painful experience: if the patient then hears his own voice autophanously he feels that it has been much altered, or is not intelligible to others; indeed, it seems to be unrecognizable to himself even. The discomfort may be increased, if such a thing be possible where the physical and mental distress is almost unbearable, by the tinnitus aurium arising from the circulatory movements taking place near enough to the ear to be heard. Loud noises, such as the passage of railway trains, street trucks, the action of machinery and the like, owing to the better transmission of their more profound impulses through unaccustomed media of approach, fall upon the nervous centre of audition like a blow and thus give rise to dysacusma.

It being doubtful if the perceptive sense of hearing be increased by labyrinthine inflammation, we may suppose that so-called hyperæsthesia of the auditory nerve consists in the painfulness of the impression made by sound on the perceptive centre. If this be true, inflammation of the perceptive filaments of the auditory nerve in the labyrinth alone would scarcely be expected to increase the hearing power. On the other hand, it would be difficult to determine what degree of labyrinthine inflammation was necessary to impair the perceptive functions. Labyrinthine inflammation, viewed from a clinical point of view, is doubtlessly nearly always consecutive to middle-ear disease, but whether existing independently or in conjunction with middle-ear trouble, the transmission of sound would be more effectually performed by means of aerial conduction as regards intelligible perception. In middle-ear disease, however, the tuning-fork would be better heard through the tissues inversely to an increasing defect in aerial transmission, but not necessarily better heard, however, on account of labyrinthine defects.

Even if the perceptive apparatus were alone affected the tuning-fork would be best heard by aerial conduction, since the transmitting apparatus affords the better conduction and at the same time interferes with osseous conduction. But cases of labyrinthine disease alone are rare, and it is difficult to establish the fact that no middle-ear disease coexists in any given instance.

CONCLUSIONS.

I. When the vibrating tuning-fork, placed on teeth or vertex is better heard through the tissues on one side, it simply indicates that the better ear excludes wholly or in part such (tissue) transmission, but it does not prove that the auditory nerve in either ear is affected.

(Of course, if the nerve of audition be gravely affected, sound will not be heard by any method of conduction.)

II. If the conductive mechanism is absent or greatly damaged in one ear, while the other remains more or less normal, aerial transmission will be found to be ineffectual in the diseased ear, while the tuning-fork allowed to vibrate as before will, therefore, be best heard in the diseased ear, and its vibrations will be almost entirely excluded from the healthy ear.

III. In deafness from labyrinthine disease, pure and simple, the middle ear being normal, the tuning-fork would be best heard, if heard in any degree, by aerial conduction, because bone conduction would be excluded.

(In those extreme cases where destructive disease of the nerve has taken place, impulses of sound may be appreciated irrespective of either the transmitting or labyrinthine structures; thus the deaf-mute is conscious of the sound of thunder, artillery, drums, stamping with the foot upon a floor, and the like.)

IV. If the above deductions be true, we may conclude that the tuning-fork is of less value than has been supposed in the differentiation of aural disease.

A CASE OF HODGKIN'S DISEASE.

By W. U. TAYLOR, M.D.,

MOORE'S, N. Y.

In September, 1882, a child was brought to my office by its father, who gave the following history: L. M——, nine years of age; French; scholar; was in usual health ("never very strong") until June, 1882, when she was poisoned by some vine while picking strawberries. Her face and hands were badly swollen, and before the swelling went down erysipelas set in, lasting about two weeks. Soon after this some enlarged glands were noticed just back of each ear. These grew rapidly and others appeared below on each side of the neck and in each axilla and groin. They grew rapidly in spite of treatment until I saw the case, and, in fact, to its termination.

On examination the cervical, axillary, and inguinal glands were found enlarged, a dozen or more in each region, varying in size from that of a pea to a hen's egg, the largest being in the right axilla. In her left groin there was an enlarged duct the size of a lead-pencil and about three inches long. All the glands except the parotids were freely movable; were firm, elastic, and without fluctuation. The parotids were enlarged, so that at the first glance I thought the child had mumps. On opening the mouth the tonsils were found greatly enlarged so as to fill the isthmus of the fauces and prevent the use of the smallest laryngoscope I had. The bronchial glands were apparently enlarged, respiration being stridulous. The liver and spleen were enlarged, there being flatness on percussion from the fourth rib to the umbilicus and the lower border could be plainly felt and its position seen. The only resonance was in the left inguinal region. The pulse was rapid and feeble, respiration shallow and frequent; skin dry and hot. Pulse, respiration, or temperature not noted at this time; appetite variable; bowels regular at present, but is subject to attacks of diarrhoea; urine scanty and high-colored. Measurements at this date were: around the head at the upper lip and angle of jaw, 17 inches; around chest, at lower border of sternum, 24 inches.

The child living at a distance, it was not seen as often as I wished. It was ordered iod. potass. with syr. iod.

¹ Read before the American Otological Society, July 17, 1883.

iron and citrate of iron and quinine, and an ointment of iod. ammonium, to be rubbed upon enlarged glands and over the abdomen.¹

October 3d and 7th.—There was apparent improvement in its general condition. Able to go up and down stairs; plays about the house; appetite good; slight diarrhoea, checked by chalk mixture.

October 12th.—Has spasmodic cough, at times attacks of "croup;" pulse, 110; temperature, 100°; had high fever the day before; said to have "taken cold." Examination of the chest gave negative results, the tracheal râles obscuring any others. Measures: around head, 17½ inches; chest, 24½ inches; at ninth rib, 25 inches; at navel, 24½ inches.

October 17th.—Very weak; confined to bed; pulse, 130; respiration, 24; temperature, 99½°.

October 21st.—Weaker; extreme dyspnoea; unable to lie down; complains of pain about the heart; urine very scanty; on standing it seems composed of urates alone; no albumen found by either heat or nitric acid; specific gravity not taken. Given infusion digitalis, 5 ss., to be repeated in six hours. Measures: Face, 18 inches; chest, 26 inches; navel, 26½ inches. Cough paroxysmal; very severe.

October 24th.—Increased dyspnoea; has "boring" pains in throat, dorsal region, and colic pains in abdomen; oedema of right arm and leg.

Died of exhaustion, October 27th, at 2 A.M. The pain and dyspnoea continued until death. Patient was conscious until a moment before she died, though drowsy from effects of anodynes. The treatment consisted of use of iod. potass., syr. iod. iron, citrate iron and quinine throughout the case. Cod-liver oil was given a short time, but causing nausea, was stopped. Concentrated diet ordered, but not carried out, the child having about what it wished. The inunction of iod. ammonium ointment was continued until it caused so much irritation as to prevent sleep. It was not used after October 17th.

During the first two weeks there was marked improvement in the general condition, but none in the glands, the enlargement progressing steadily until death occurred.

The child was about the house and ate at the table until October 17th. After that there were several days when she was apparently better.

Authorities seem agreed as to the unfavorable termination of these cases, and it may be said of them as Dr. C. was wont to say, in lecturing upon "croup": "Gentle-MEN! If you have a case of *true* mem-branous croup—and it gets *well*—it's NOT CROUP!"

SYPHILITIC MAMMARY DISEASE.

REPORT OF A CASE OF INHERITED SYPHILIS—REMOVAL OF MAMMARY TUMORS BY THOMAS' METHOD—AFTER TREATMENT BY THE IODIDES.

By CHARLES C. F. GAY, M.D.,

SURGEON TO THE BUFFALO (N. Y.) GENERAL HOSPITAL.

I HAVE recently had under observation a case of so much interest to myself that I have thought report of it would be of interest also to the profession. Miss C. M—, aged nineteen years, came under my charge on March 7, 1883. She is an only child; her health had been good until four years ago, when she began to have pain in both mammary glands; more especially the left one. The glands were well developed.

During these four years she had been a great sufferer. The left breast became so sensitive that the weight of the bedclothes upon it could not be borne. Her menstruation was regular and in no way influenced the pain of the mammary gland, either to lessen or increase it. A day or two before the patient came to me, she was examined by the gynecologist of the hospital, who reported

the hymen unruptured. There was no question raised whatever against the virtue and morals of the patient. She was well educated, cultivated, and refined. Her left breast was hard, nodular; felt like scirrhus and would have been so pronounced, I am quite sure, had her age been forty-five instead of nineteen years. The breast was so excessively tender to the touch, that it could not well be examined without ether; the nipples were retracted. At a consultation, the tumors were pronounced non-malignant, but removal was advised. The young woman stated that eighteen years ago her father had a cancer cut out from his throat; but as the father was still living, this statement of the nature of his ailment was regarded as apocryphal, and did not contribute toward a diagnosis of cancer in the case of the daughter. There appeared to be three or four tumors of the size of a hickory nut in the left, and one of smaller size in the right breast. The patient was extremely anxious to have these tumors removed as soon as possible, and had travelled a considerable distance in order to have an operation performed, and as removal was decided upon at the consultation, the patient was, on March 14th, etherized, and Thomas' method for removal of benign tumors employed. This method consists in making a semicircular incision around the lower half of the circumference of the breast, in the crease formed by the junction of the gland with the chest, dissecting up the gland and turning it inside out. This being done, examination showed that the tumors so much involved the gland itself, as to necessitate removal of the greater portion of it. The integument was replaced, secured by sutures, and the wound treated antiseptically with the boro-glyceride.

In three weeks there was no union, nor signs of union, in any part of the wound; it looked and smelled like a syphilitic ulcer, and the tendency to disintegration preponderated over the process of repair. Diagnosis of syphilis was made, and the iodides of mercury and potash employed at once. In four days the whitish stroma was removed, and in its place red and healthy granulations appeared; the offensive odor was dispelled, and in three weeks more the wound was closed. After our patient left for home, search of the hospital records was made for the father's case and his record found, from which I learned that he entered the hospital with syphilis when our patient was a child just four months of age. He remained only a few days, but returned again four times during a period of two years. He entered the hospital twice for syphilis, once for secondary, and once for tertiary syphilis. It is fair to conclude, that this man had the primary lesion months before his first entrance to the hospital, and long before the birth of the child. His disease was recognized as syphilis at that time by the attending surgeon, and the record accordingly made. There is no record of cancer nor of removal of a cancerous tumor. The immediate effect of the anti-syphilitic treatment employed, in case of the young woman, proved the correctness of the diagnosis, and it was confirmed and corroborated by the hospital records. The records furnished sufficient evidence to establish the fact that the disease was inherited; that the poor child was conceived in sin and endured suffering in consequence thereof. The mother was pregnant but once, and her health had been impaired for a long time.

The conclusion is, that the husband communicated the disease to the wife, and she in turn gave it to the child in embryo; that the taint remained latent for a period of years, and at length manifested itself in the mammary glands. If one could have diagnosed the disease and have treated the patient for specific disease, the mammary tumors might have been dispersed and an operation forestalled. This, however, is conjectural only. The operation resulted in substantial benefit. The right recovered soon after the performance of the operation upon

¹ New York Medical Journal, vol. xxxv., p. 337, 1882.

the left breast. Whether it were neuralgic induration or an affection arising from sympathy with disease of the left breast, I have no means of judging. I am led, however, to suspect that in an occasional instance the so-called "neuralgic indurated breast," and the "painful breast" of authors, might be classed under the head of syphilitic mammary disease.

Progress of Medical Science.

ACUTE ANASARCA WITHOUT ALBUMINURIA IN PREGNANCY.—The following case is related by Dr. M. H. Rendu in *La France Médicale* of April 19, 1883. A woman, twenty-two years of age, pregnant for the second time, suffered greatly from fatigue and anxiety while nursing her first child, who was sick with meningitis. She took cold, as she supposed, one night toward the end of the child's sickness, and had repeated chills with lumbar pains and general weakness. Soon a persistent headache supervened, accompanied by nausea and anorexia, but without vomiting. About five days later the patient noticed that her legs were swollen, and the anasarca in a short time became general, but was especially marked in the eyelids and breasts. The pulse was 110; temperature, 103.5°. The urine was scanty, less than thirty ounces being passed in twenty-four hours, was red in color and deposited urates in abundance. It contained, however, no trace of albumen, although daily examinations were made for a month. The other organs seemed healthy, the heart was normal, and there was no history of recent scarlatina. The patient was placed on milk diet and diuretic remedies, but continued to grow worse until it was feared that œdema of the brain would ensue and give rise to eclampsia, or that the patient would die from pulmonary œdema. It was then decided to bleed the woman, and accordingly between nine and ten ounces of blood were taken. At the same time numerous punctures with a fine needle were made in the swollen vulva and legs, giving exit to an abundant flow of serum. Improvement at once set in, and every trace of œdema had disappeared in two weeks.

DIAGNOSIS OF THE DIFFERENT FORMS OF URETHRAL DISCHARGE.—Dr. Fürbinger thus distinguishes the different discharges taking place from the male urethra (*Centralb. für klin. Medicin*, April 21, 1883). Spermatorrhœa is a loss of seminal fluid which occurs during defecation or at the completion of micturition. The condition, which is much more common than is ordinarily supposed, is not a final stage of pollutions, but is caused most frequently by gonorrhœa and sexual abuses. Spermatorrhœa becomes azoö-spermatorrhœa when for any cause (usually from epididymitis) the testicles cease to produce spermatozoa. Prostatorrhœa is the discharge, sometimes continuous, sometimes only during defecation and urination, of the prostatic secretion. It is a rare condition, and is a symptom of chronic prostatitis, usually of gonorrhœal origin. Urethrorrhœa ex libidine is a phenomenon occurring usually in anemic and nervous individuals. It consists of a scanty discharge, without orgasm or ejaculation, accompanied by intense sexual excitement and strong erection. The last discharge to be considered is gleet.

Of these five processes two are easily recognized. Spermatorrhœa is evidenced by the presence in large numbers of spermatozoa (a few here and there signify nothing), and urethrorrhœa is readily recognized by its characteristic mode of onset. The secretion of the latter is the product of the urethral glands and Cowper's glands. It is clear, stringy, and contains but few epithelial and round cells. A very abundant discharge points to azoö-spermatorrhœa. The absence of pus-corpuscles also points to the same condition, though their presence has no weight on the other side, as urethritis

may exist at the same time. In such cases the presence of the specific secretion of the seminal vesicles must be determined. If one finds a jelly-like substance resembling in shape grains of sago, that is conclusive; but if this is not found, it may be that it is in solution, and may then be precipitated by a strong alkali. The secretion is allowed to stand for a time, and then a clear drop is placed in a watch-glass, and a drop of caustic potash added. If now the drop shows a thick white cloud, or streaks, it is evidence that the secretion contains seminal fluid. If this process shows that we have not to do with azoö-spermatorrhœa, there still remains the differential diagnosis between prostatorrhœa and gleet to be determined. In the latter the discharge is very scanty; in the former, digital examination reveals great tenderness on pressure of the prostate gland. Indications of prostatorrhœa are: 1, the presence, unfortunately not constant, of numerous amyloid bodies; 2, numerous typical cylinder cells, especially when in the double layer arrangement of glandular epithelium; 3, the large Böttcher's crystals. The presence of the latter is ascertained by mixing a drop of the secretion with a drop of a 1 per cent. solution of phosphorated ammonia upon an object glass. In about an hour numerous large, exceedingly beautiful crystals are formed. The secretion of the prostate, the author insists, is not clear, odorless and thick, as usually stated, but is thin, of a milky cloudiness, and possesses the characteristic odor of spermatic fluid.

An aid to diagnosis is also found in the time of the appearance of the secretion in the urine. The first and last portions are to be separated from the principal flow of the urine. The presence of the secretion in the first portion points to gleet; in the first and second portions to prostatorrhœa; in the third portion to azoö-spermatorrhœa. The latter appears in the form of nearly transparent, thick, stringy masses, and sometimes also in the shape of sago grains.

A RARE FORM OF IMPERFORATE ANUS.—Dr. Ramonet relates the case of a child, three days old, who was brought to him on account of imperforate anus. There were up to that time no symptoms of strangulation of the bowels. The perineum presented a perfectly plane surface without elevation or depression to indicate the point at which the rectum terminated. But at the upper and posterior part of the scrotum, at the median raphe, there was a small orifice through which a little meconium escaped. A sound introduced into this orifice could be passed backward just beneath the integument to the point at which the anus ought to be. The operation showed that there was no deviation of the rectum; it was well formed and ended in the normal situation. The anus, instead of opening directly, formed an elbow beneath the skin and terminated with a fistulous opening at the root of the scrotum.—*Revue Médicale*, May 12, 1883.

RESECTION OF THE WRIST.—From a careful study of upward of sixty cases of resection of the wrist, Dr. G. Nepveu is not led to think very highly of the operation as regards either the cure of the disease or the restoration of function of the joint (*Revue de Chirurgie*, May, 1883). The following conclusions are formulated by him: 1. Resection of the wrist is not usually dangerous to life, especially when performed under antiseptic precautions. 2. A good result is sometimes obtained in the cure of the local disease and restoration of function. 3. This is, however, rare, occurring in not more than one-fourth of the cases. More frequently the cure of the disease is incomplete and the restoration of function but partial. 4. A more grave termination is not uncommon: sometimes death ensues, and sometimes, owing to non-arrest of the disease, amputation is required. 5. One cause of this want of success in resections of the wrist is that the operation is often undertaken in unfavorable cases. The operation is contra-indicated in osteitis and

in synovitis with tubercular deposits. 6. To obtain the best results as regards the usefulness of the joint, as little as possible of the bone should be removed and the periosteum should be preserved as far as the conditions of the case will permit. 7. An operation should never be had recourse to until all conservative therapeutical measures have proved unavailing. Such measures are immobilization, compression, counter-irritation, prolonged antiseptic lotions, etc.

IMMUNITY OF COPPER WORKERS FROM CONTAGIOUS DISEASES.—At a recent meeting of the *Société de Biologie* of Paris, Dr. Burq presented an interesting communication upon the immunity enjoyed by workers in copper during epidemics of cholera and typhoid fever (*La Tribune Médicale*, April 29, 1883). He stated that of forty thousand such workmen, two only died during each of the epidemics of typhoid fever in 1876 and 1883. Furthermore, the statistics of a society of three hundred members, all copper workers, showed that during the entire period of the existence of the organization (sixty-four years) there had been but three deaths from epidemic diseases among its members.

SYPHILITIC LIVER IN A BOY.—Dr. Teissier relates the case of a boy, fifteen years of age, who came under his care suffering from ascites; there was also diarrhoea and a slight cough. The diagnosis was made of tuberculosis of the peritoneum, intestines, and lungs. Paracentesis was performed several times and the child was put upon a tonic and diuretic treatment, but he sank rapidly and died. At the autopsy there were no tubercles discoverable in any of the organs or serous membranes. Of all the viscera, the liver alone showed any changes. It was rather small and presented upon its surface yellow nodules, hard as a stone and covered with a fibrous envelope. This latter sent out white fibrous prolongations, following the course of Glisson's capsule, and giving to the liver a lobulated appearance. Examination, both macroscopical and microscopical, showed the case to be syphilis of the liver, and this was further confirmed by the statement of the parents that the child had acquired "a disease" from his nurse.—*Lyon Médical*, May 13, 1883.

CHRONIC MYOCARDITIS AND DISEASES OF THE CORONARY ARTERIES.—Cases frequently occur—more particularly among well-to-do people, more rarely in the poorer class of persons over middle age—in which death occurs suddenly, without previous symptoms, excepting, perhaps, a feeling of constriction or pain at the chest. Dr. Carl Huber (*Virchow's Archiv*) gives a number of such cases in which the cause of death appeared to be sclerosis of the coronary arteries, and subsequent chronic myocarditis. The consequences of this myocarditis are aneurism of the heart, thrombosis, dilatation, and hypertrophy. The clinical symptoms are angina pectoris, stenocardia, and asthma. These symptoms generally occurred in paroxysms some months before death, generally after excitement, either bodily or mental, several times after dinners. In some there was irregularity or intermittence of the pulse, occasionally cardiac bruits; sometimes there was a sudden giddiness with temporary loss of consciousness on stooping, walking quickly, or going up stairs. The attacks were sometimes also accompanied by symptoms of collapse. Death sometimes occurred almost at once, but at other times several minutes, hours, or even days elapsed, during which time there were the symptoms of cerebral apoplexy, paralytic conditions, and alterations in the cardiac rhythm. The peculiarity of this cardiac affection is that it has nothing whatever to do with endocardial or pericardial disease, but depends on arterial sclerosis. Cardiac apoplexy, the author considers, is a condition to be reinstated in its old place as a well-marked disease, like cerebral apoplexy. It sometimes occurs in young individuals, the general cause of such occurrence being alcoholism or syphilis.

THE EFFECTS OF DISEASE ON THE SIZE OF THE HEART.—This subject has been investigated by Dr. Spetz (*Deutsches Archiv für klin. Medizin.*). He finds that in typhus there is no characteristic change in the dimensions of the heart and the large vessels; the same is the case in puerperal pyæmia. In phthisis the heart is diminished, and especially the left ventricle. The right ventricle is often somewhat diminished, but not in proportion to the diminution in the weight of the body. It is sometimes even hypertrophied, but not as a rule. The ratio between the depth of the left ventricle and the circumference of the aorta is diminished, and as this is not compensated for by hypertrophy of the muscular walls of the ventricle, there is a diminution in the arterial tension. Consequently the pulse in phthisis is soft and small. In cancer the depth of the left ventricle is still more diminished than in phthisis, and the right ventricle is affected almost as much as the left. In granular kidney, both ventricles increase very much, but especially the left. The aorta is not correspondingly dilated. In consequence of this the tension in the arteries is very greatly increased. In myocarditis, also, the heart is dilated and hypertrophied, but the left and right ventricle are almost equally affected. In chronic emphysema both ventricles are much dilated, with very little thickening of the muscular walls. Both ventricles are nearly equally affected. The pulse is full, but small and languid.

MODE OF REPRODUCTION OF THE LIVER.—While conducting some experiments upon the spleen of a dog, Dr. Tizzoni accidentally wounded the liver at the edge of one of its lobes. Six months later he discovered a tumor at the exact point where the wound of the liver had been made. It had all the gross appearances of the liver-substance. A portion was treated with bichromate of potassium and alcohol, and then numerous transverse and longitudinal sections were made. From a study of these the author arrived at the following conclusions: 1. Under certain circumstances the liver may be reproduced at the point where it has been wounded; there is a new formation of hepatic cells and biliary ducts. 2. Unlike what occurs in the spleen, the great omentum adherent to the wound in the liver does not take part in the reproduction of the substance of the organ, but serves merely as the stroma in which the newly formed tissue arises and is developed. 3. The new tissue arises from the pre-existing hepatic cells, which, by cellular multiplication, send out offshoots which penetrate into the epiploön like the prolongations of an epithelial tumor in the connective tissue of the skin; the hepatic cells present numerous nuclei, sometimes as many as twelve, which are deeply stained by carmine. 4. Some of these cellular prolongations have a light centre and assume the appearance of bile-ducts, while others are filled with protoplasm and nuclei, and resemble then the hepatic cells. 5. The newly formed hepatic cells, which resemble histologically the old ones, have that in common with the hepatic cells of the embryo that they remain for a long time separated by true lacunæ filled with blood. 6. The acinous disposition is wanting, but large blood-vessels, especially veins, and biliary ducts can be seen. The author concludes from this that the regeneration of the liver is in all points identical with the embryonic development as described by Remak and Kölliker.—*Journal de Médecine de Paris*, April 28, 1883.

NAPHTHALINE IN FROST-BITES.—Dr. Lindenbaum has employed this remedy with success in a number of cases of frost-bite. The dressing is usually changed every seven to ten days. In some instances the patients complained for two or three hours after the application of severe sticking pains, caused probably by small crystals of naphthaline. As far as the author's experience will permit him to judge, the same remedy is equally beneficial in burns.—*St. Petersburger Med. Wochenschrift*, June 2, 1883.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 28, 1883.

"THINGS WHICH [CANNOT BE SHAKEN.]"

UNDER the above heading the readers of a popular religious weekly have lately been entertained with a series of articles by an eminent theologian, who showed the applicability of this text to the dogmas which he professed. As medical men we are especially interested in knowing how far the text may be applied to the therapeutic doctrines which we hold.

To go at the subject in sermon-like fashion, we ought first of all to premise that much has been taught as medical truth which has been shaken, and shaken to pieces. Secondly, we might show that much is still taught in physiology, pathology, therapeutics, which will probably be shaken. Thirdly, we should consider the things which cannot be shaken.

Under the first head would come all absurdities which have characterized medical practice in the past, of which we will only mention the doctrine of the four humors; the psora theory of constitutional diseases; the doctrine of signatures; in short, all the crudities and abominations in theory and practice which were the offspring of ignorance or superstition.

The second head we hardly dare touch upon for fear of being called iconoclastic. There is much in current medical teaching which we venture to affirm may possibly be shaken. Thus, in physiology, we do not think that the functions of the cortex cerebri, of the basal ganglia, of the cerebellum, of the vasomotor nerves, of the spleen, the current theories of menstruation, the hæmatopoietic functions of the blood, vascular glands, and the spinal marrow, etc., are yet settled, so that important modifications may not yet be made in the views now held. In pathology it will doubtless be proved that false ideas are now prevalent as to inflammation, tuberculosis, the pathogeny of infectious diseases, etc.

In therapeutics how much will escape the condemnation of future criticism none can tell. Our best text-books are full of untruths, partial truths, and exaggerations. It is so in regular medicine, and it is so in homœopathy. Refer to any drug in any treatise on materia medica—calomel, antimony, arsenic, aconite, phosphorus, etc., and you will find medicinal virtues ascribed that have never been realized, and much that is as fanciful as the "provings" of the infinitesimals.

We come now to our third and last head. While we would express ourselves with due modesty and caution, we affirm that the great body of medical doctrine, outside

of therapeutics, is "unshaken as the sacred hills." There is no room for doubt as to the origin, insertion, and uses of the flexor longus pollicis; that gastric juice has a solvent action on food; that the ligature of a bleeding vessel stops hemorrhage. Our concern now is principally with therapeutics, for it is there that we brethren of one family disagree. It is because there is so much that can be shaken that there are so many divisions in medicine. As far as medicine is an exact science there is no rational basis for differences of opinion. There are no sects or pathies in science, nor will there be in therapeutics when the actions of drugs and their relation to diseased states of the economy are definitely known.

Truths must ever stand as firm as mountains. What we want above all things is to get at facts. Some medical tenets may be accepted provisionally as probable; here we must act to a certain extent "by faith." With regard to others we have a tolerable degree of certainty. There are numerous medicaments whose physiological effects have been sufficiently determined to warrant dogmatism with regard to them. Under such and such circumstances, certain positive results will be obtained. The same may be said of their therapeutical effects, as determined by clinical experience. Among these drugs we may specify bromide of potassium, chloral, belladonna (in part), digitalis, nux vomica, opium, ergot (to some extent), and many cathartics. With regard to the action of anæsthetics, there can be no doubt practitioners of all schools utilize ether and chloroform when the urgent indication is to relieve violent pain or spasm or to produce anæsthesia for a severe surgical operation.

If we were all as fully agreed on the actions and uses of other medicaments as we are on the actions and uses of those just mentioned, and especially the bromides, when we wish to depress reflex spinal irritability, opium and anæsthetics when we wish to relieve pain or produce insensibility, we are certain that there would no longer be any sects in medicine. Progress in therapeutics is fast tending in this direction. It is no use ignoring the fact. We are learning more of pathological states, of etiology, of accurate diagnosis, and our knowledge is fast being reduced to system. Disease being only morbid physiology, physiology aided by etiology is becoming the intelligent guide of the therapist. What shall restore the disordered organ to its normal state, if any restoration be possible? How far may hygiene contribute toward this end? How far medicine? This is the problem for which we are seeking exact data. Earnest workers in all lands are contributing to our knowledge. The past twenty years have witnessed a great advance. The "regular" of to-day who has kept up with the age might find little common ground with the "regular" of a bygone generation. What shall be the final outcome of this movement toward more complete knowledge and therapeutic unity and harmony?

THE THERMOMETER IN THE DIAGNOSIS OF STOMACH DISEASES.

SOME time ago M. Peter made some investigations into the changes in surface-temperature in lung diseases. He claimed that by careful measurements slight changes in temperature could be observed over the seat of congestive or inflammatory foci in the lung tissue. By his

method an earlier and more certain diagnosis of phthisical troubles could, in the investigator's opinion, be made. Not much use has been made of M. Peter's observations, either to refute or confirm them. The cost of sufficiently delicate instruments, the difficulty of making a sufficient number of examinations, and the problematical value of the results explains this.

Not discouraged, however, M. Peter is continuing his investigations, and now directs his attention to variations of surface temperature in diseases of the abdominal viscera. Some preliminary reports have been made in the *Gazette des Hôpitaux*. These refer to diseases of the stomach. There is no doubt that differences in the condition of this organ cause corresponding changes in the cutaneous surface over it. This is so strictly the case that careful observations have detected a constant difference in the temperature of the skin over the pylorus from that of the fundus. This difference varies between $.1^{\circ}$ and 1° C., or from $\frac{1}{8}$ to nearly 2° F. The normal surface temperature over the stomach, as determined by Levin and by Peter, was from 34.9° to 35.9° C. (94.6° to 96.5° F.). It is higher in the morning, sinks toward noon, rises for the first three or four hours after meals, then sinks. M. Peter has thought that by studying these local variations he can obtain great help in the differential diagnosis between simple neuralgic and inflammatory conditions of the stomach. In a case of gastric ulcer, he found the temperature over the stomach to vary between 37° C. (98.5° F.) and 38.2° C., that in the axilla being 36.8° to 37° C. In a case of alcoholic gastritis, he found it to vary between 36.8° and 37° C. On the other hand, in gastralgia, he found very little change from the normal, that change occurring only in the most excessive exacerbations of pain.

The distinguished Frenchman seems to be unaware that this subject has been investigated to some extent before, and with interesting results. In 1879 Levin wrote an article entitled "La Thermometrie de la Region Stomachale," in which he stated, among other things, that the local temperature in dyspepsia (after eating) and in cancer and dilatation of the stomach was increased 1° to 2° C. above the normal.

So far, the results of this kind of surface thermometry have been small. Yet they tend to show that there is a definite temperature relation between the stomach and the skin over it.

THE READING OF MEDICAL BOOKS TO JURIES.

THE propriety of reading medical books to a jury has been often questioned, and the courts of many of the States refuse to allow it. In a recent case in Wisconsin it was held that such books could not be read nor extracts be given therefrom by physicians from memory, nor could they be read by counsel on the argument. In "Rogers' Expert Testimony" it is stated that evidence of this kind is not admissible in Indiana, Maine, Maryland, Massachusetts, Michigan, North Carolina, Rhode Island, Wisconsin, California, and New Hampshire, and is admissible in Iowa and Alabama.

The case above referred to was a trial for murder, and the Court said, "The effect of the evidence given, under objection, by Dr. Cody was to put before the jury as evidence what the medical works laid down as evidences of

strangulation. If this may be done indirectly by the oral testimony of the person who has read the medical works, it would certainly be a much safer rule to permit the books themselves to be read to the jury, as being better evidence of the fact. We think the learned Circuit Judge also erred in permitting the counsel for the State to read the medical authorities to the jury in the opening of his argument. It is evident they were not read by way of illustrating the argument of the counsel, but to give the jury a clear view of what such medical writers laid down as the evidence of strangulation. The jury must have understood that the extracts read to them were so read for the purpose of having them considered in determining the question of fact whether the deceased came to her death by strangulation."

THE RIGHTS OF CORONERS TO HOLD INQUESTS.

THE extent of a coroner's right to hold an inquest has come before a Pennsylvania Court for decision, in a case where the family of the deceased strenuously resisted the attempt to hold an inquest, and insisted that the circumstances of the death made an inquest not only unnecessary, but an outrage.

The facts were that the deceased was an old man about eighty years of age and had been ill for several days, but was under the care of Dr. Atlee, a reputable physician of the city of Lancaster. The deceased died in his own house and surrounded by his family.

The disease was paralysis, and when the coroner, against all remonstrances, persisted in the inquest, the verdict brought in was "death from a paralytic stroke." Upon the trial the main question litigated was whether a coroner was a judicial officer in the sense that he was the only judge of the propriety of exercising the functions of his office. The Court repudiated this theory of a coroner's duties, and held that an inquest could only be properly held where there was a reasonable ground of believing that death was caused by violence or some other unusual means.

It was further stated that if an inquest could be held in a case like that stated, it would be permissible to make a post-mortem examination, an idea "preposterous and abhorrent to all the finer emotions of human nature."

A bill was presented to the Legislature of this State for the abolition of the coroner's office and the substitution of a board of medical experts.

The tendency seems to be setting strongly toward the opinion that a coroner's inquest is of comparatively little importance in determining the correct causes of deaths by violence, and if in addition to this it is found that coroners claim the right to hold inquests at their own sweet will, without regard to the circumstances of the case, it cannot certainly be long before the Legislature will abolish the whole system.

THE THIRD BLOOD-CORPUSCLE.

MUCH attention has been paid to the so-called third blood-corpuscle, or hæmatoblast, by various physiologists, and especially by Schultze, Hayem, Norris, Hoffman, Bizzozero, and lately by Carl Laker and Friedr. Rauschenbach.

Bizzozero's views are now quite well known. He believes that the blood of cold and warm-blooded animals

contains blood-disks, with parallel surfaces, one-half or one-third smaller than the red blood-corpuscle. Hayem describes them as small biconcave disks, of a slightly yellowish color. Laker recently confirms Hayem's view as to their shape, but thinks the yellow color artificial. Norris, like Hayem, considers them biconcave, but doubt has been thrown over the accuracy of his observations because he describes them as of nearly the same shape and size as the red blood-corpuscle.

The actual number of these bodies, as well as their physiological importance, must be very much greater than has been hitherto supposed, if we may believe the more recent investigations. Norris estimates that his colorless corpuscles rank in number between the white and red. Bizzozero does not venture any estimate. Laker, who has devised some special methods of coloring and studying them, counted in one field 180 blood-disks or hæmatoblasts, 44 red, and 9 white corpuscles; in another field the ratio was 830, 270, 0. This estimate, however, cannot give a true idea of their actual proportions in the blood.

It is as yet impossible to say whether these corpuscles precede the red or follow them in their development.

Their function has of late been studied with special reference to their relation to the process of coagulation. The prevailing view regarding the origin of the fibrin-factors has been heretofore that of A. Schmidt's, viz.: that while fibrinogen exists in the plasma, the fibrinoplastin and ferment are contained chiefly in the white blood-corpuscles; these latter dying, give up their factors, and fibrin is formed. Hoffman has claimed that in coagulation 71 per cent. of the white corpuscles are used up and destroyed.

Landois and others had, however, shown that the red corpuscles are also apparently concerned in fibrin-building, and Hayem has recently been arguing that the hæmatoblasts, not the white cells, are the chief contributors to the process. Three investigators, Laker, Bizzozero, and Rauschenbach, now come to his support, and cite evidence to show that the hæmatoblasts do play this important part. It is found, for example, that proplastic fluids like that of hydrocele, which contain fibrinogen but not the other factors of coagulation, do not coagulate when the fluid from the spleen or lymphatic glands, so rich in leucocytes, is added, but do so on the addition of the little blood-disks.

The evidence so far shows that the blood contains a third corpuscle, which plays a part in the process of coagulation; also that the factors in coagulation are derived not from any of the different blood-elements alone.

The extremely important part which fibrin and its factors play in septic fevers, when it is often rapidly developed with great rapidity and in extraordinary amounts, makes the study of its origin an interesting one. Recent experimental studies of Maissurians ("Inang. Diss.," Dorpat) upon the changes of the coagulability of blood in fever have shown this very strikingly. The importance of the coagulation process in its relation to operative surgery lends a further interest to the investigations into its ultimate nature.

THE HONOR OF KNIGHTHOOD has been offered to Dr. Pitman, Registrar of the Royal College of Physicians.

News of the Week.

THE INFLUENCE OF THE DOCTOR IN HEALTH RESORTS.—"Each winter resort," says John Richard Green in "Stray Studies," "brings home to us the power of the British doctor. It is he who rears pleasant towns at the foot of the Pyrenees, and lines the sunny coasts of the Riviera with villas that gleam white among the olive groves. It is his finger that stirs the camels of Algeria, the donkeys of Palestine, the Nile boats of Egypt. At the first frosts of November the doctor marshals his wild geese for their winter flitting, and the long train streams off, grumbling, but obedient, to the little Britains of the south."

BROMIDE OF SODIUM IN SEA-SICKNESS.—Mr. T. M. Kendall reports (*British Medical Journal*) the results of his treatment of two hundred cases of sea-sickness. He confirms the views of the late Dr. Beard, that bromide of sodium is the most efficient of all remedies. He found that in doses of ten grains, three times a day, it was effectual. Mr. Kendall condemns the too indiscriminate use of oranges, lemons, champagne, and brandy.

A POST-GRADUATE SCHOOL in Philadelphia has been organized in connection with Jefferson Medical College.

THE NEW MICHIGAN MEDICAL REGISTRATION LAW, which was approved June 6th, will go into effect on September 6, 1883. It allows all persons who have been in practice for five years, or who are regular graduates from legally incorporated medical colleges to register at the county clerk's office. It is made a misdemeanor for any person to practise without registering. The supervisor is required to make annually a statement of the number of physicians in his district. There appears to be lacking any machinery for carrying out the law efficiently. The *Medical Age* says: "The profession were given no opportunity to be heard on it during its passage, and although it was introduced by a physician it is eminently laymanlike in its construction. The hand of the lawyer is, moreover, very conspicuous in the absence of the faintest shadow of it. It is clear, from the careful perusal we have given it, that the number of doctors in Michigan cannot be increased after December 6th next, and until the act has been amended so as to permit of such increase. It is expressly provided that all registrations shall be made during the three months following the date on which the act takes effect (September 6th to December 6th), and no provision is made for those who may wish to commence practice in the State subsequently to December 6, 1883. This may have been designed by the framer of the bill. But whether a design or a blunder, all future graduates and students of our Michigan medical colleges, as well as all graduates and students from the colleges of other States and countries, will, it appears, be obliged to settle elsewhere than in this State while the provisions of our new medical act remain operative.

TELEPHONIC CONNECTION BETWEEN HOSPITALS AND THE ATTENDING STAFF.—The treasurer of St. Bartholomew's Hospital, London, has completed arrangements with a telephone company with a view of placing the principal hospitals in London in direct telephonic com-

munication with the surgeons and physicians belonging to those institutions. The scheme proposed is that the various hospitals should be made the centre of communication, that the telephone company should connect the large hospitals with the nearest telephonic exchange, free of any charge, the company being remunerated by the payments to be made by the surgeons and physicians for connecting their private residences with the exchange.

EXAMINATIONS IN STATE MEDICINE.—The Royal College of Physicians intends to institute an examination in State Medicine.

DR. JOHN A. OCTERLONY has been appointed Professor of Obstetrics and Diseases of Women and Children in the University of Louisville. The university is to be congratulated.

THE DRAKE MEDICAL SOCIETY is the title of a new and enterprising organization recently established in Cincinnati, O.

HOW TO DEAL WITH CHOLERA.—The *Lancet* takes a very positive and hopeful view of our ability to cope with cholera. It seems strange that the disease should so persistently spread when disinfection will so promptly stop it. The fact is, the *Lancet* is too sure of its statements. Cholera can be checked, but it cannot always be at once stopped by any method if it once gets a strong foothold. Our contemporary says: "What, however, we do assert, is that medicine, as a preventive art, in its dealings with the germs of disease, ought to be able to grapple instantly and successfully with cholera. We know that it is propagated solely through excreta, and that water is the great carrier of the infective germs. Obviously, if the excreta of a cholera patient are allowed to dry in contact with the air, they may float away in the atmosphere, and the air will then become infected; but in a primary sense it is the water to which we must look. In any case, it has been demonstrated that, provided all the excreta from a cholera patient are instantly destroyed—not merely disinfected—the disease will not spread. The malady can no more develop *de novo* than a plant can grow without seed. It is no use waiting until the disease has effected a lodgment in our midst. If choleraic dejecta have passed into the sewers before the nature of the disease has been recognized, as is most likely to happen, the seed has been already sown broadcast, and the production of a crop of cases in some locality—it may be seemingly far from the first case, but in connection with it—will be inevitable. The only effectual safeguard against the epidemic we desire to avoid is to begin at once to destroy *all* diarrhoea stools, lest too late they may be found to have been choleraic! As a matter of precaution we ought always to destroy the stools of fever and diarrhoea. It is wanton recklessness to allow them to pass into the sewers. This is how disease is spread and perpetuated, when it should be stamped out. Whatever disinfectant we employ should be used *at once*, and of strength sufficient to accomplish the object in view. These are hints which should be reduced to practice without delay."

THE SANITARY INSTITUTE of Great Britain will meet at Glasgow, September 25th to 29th.

GOLD MEDAL TO DR. BROWN-SÉQUARD.—The Royal College of Physicians has awarded the gold medal, founded in memory of the late Dr. Baly, as a mark of distinction in physiology, to Dr. Brown-Séquard.

DR. BENJAMIN BALL has been elected a member of the Académie de Médecine.

AMBULANCE SERVICE IN PHILADELPHIA.—The committee on Medical Charities of the Philadelphia Society for organizing charity, says the *Philadelphia Medical Times*, announced at a recent meeting that steps had been taken to supply all the police-stations with hand-ambulance wagons, and before very long every station-house will be supplied. In some of the stations they have been already in active use for nearly two years.

THE NEW JERSEY STATE DENTAL ASSOCIATION held its annual meeting at Asbury Park, July 18th and 19th.

IOWA VITAL STATISTICS.—The Secretary of the State Board of Health has just tabulated his returns for 1882. The number of births reported for the year was 7,753; marriages, 5,282; deaths, 10,059; still-births, 225. Scott County reports the birth of 22 pairs of twins, leading the State, but Marion and Warren Counties, lying side by side, return 20 each. Clark is the only county reporting triplets. Despite twins and triplets the death-rate is unusually larger than the birth-rate, an ominous condition of affairs.

THE BRISTOL MEDICO-CHIRURGICAL JOURNAL is the title of a new provincial journal, published under the auspices of the Bristol Medico-Chirurgical Society, and edited by J. Greig Smith. It contains a large amount of original matter, is well illustrated, but printing and paper are not quite up to British standards.

PROSECUTING IRREGULAR PRACTITIONERS IN CANADA.—At the triennial meeting of the College of Physicians and Surgeons, Province of Quebec, held at Quebec, July 11th, the president reported that systematic proceedings had been undertaken to prosecute violations of the medical act. Forty-nine suits were instituted, of which thirty-five were successful.

THE COLLEGE OF PHYSICIANS AND SURGEONS of this city has sustained a loss in the resignation of Professor Dalton from the Chair of Physiology. It is understood that the resignation is due to Professor Dalton's ill health. He is succeeded by Dr. John G. Curtis.

THE CENTRAL ASSOCIATION OF BOHEMIAN PHYSICIANS held its annual meeting at Kommutau on July 14th. Papers were read by Professors Chiari and Breiskey, and others.

THE ANATOMICAL BILL, legalizing the use for scientific purposes of dead bodies, has failed in the Georgia Legislature. The *Register* says that bodies will now be scientifically snatched.

CORONERS IN CONNECTICUT.—The Legislature of Connecticut has passed a law requiring that coroners in that State shall hereafter be attorneys-at-law, familiar with criminal practice and medical jurisprudence, and that one such person for each county shall be recommended by the State's attorney for such county to, and be appointed by, the judges of the superior court to

hold his office for the term of three years, and until another shall be duly appointed in his stead, unless sooner removed from office for cause. And the said coroner is required to appoint for each town of the county "an able and discreet person, learned in medical science, to be medical examiner." Upon these officers is devolved all the duties in detail which have hitherto *not* been exercised by coroners under the old régime, and such as are common throughout the United States outside of this commonwealth.

THE HOSPITAL CHAPLAINS have been withdrawn from the Paris hospitals despite some very earnest protests.

THE COUNT DE CHAMBORD.—Germany and France have united over the body of the sick king, but have not agreed as to his condition. Professors Billroth, Dratsche, Wiener, and Bamberger came all the way from Germany to view him, and Vulpian, with other eminent Parisians, have been in consultation. It is agreed that he is obese, has a fatty heart, and gastric derangement. Some have said that he was suffering from phlebitis.

DR. W. B. RIZNER, a prominent physician of Cleveland, O., dropped dead in his residence in that city on July 21st. He was fifty-nine years of age. He was the inventor of a mechanical finger used in microscopy, and President of the Cleveland Microscopical Society.

THE HUNTER'S POINT NUISANCES.—The Governor and the State Board of Health have for some time been quietly collecting evidence against the various Hunter's Point factories, and on the 24th thirty-two of them were surprised with an order forbidding any further stench-making manufactures. The penalty for disobedience is \$1,000, and two years' imprisonment.

Correspondence.

OUR PARIS LETTER.

CONTAGIOUSNESS OF PHTHISIS—THE LEAGUE AGAINST VIVISECTION—ASYLUMS FOR CHILDREN—NACHTEL'S AMBULANCE SYSTEM—COUNT DE CHAMBORD.

PARIS, July 16, 1883.

DR. DEBOVE, who was appointed temporarily to take charge of the late Professor Lasègue's wards at "La Pitié" Hospital, lately delivered a most interesting clinical lecture, in which he endeavored to demonstrate, by cases under his immediate care, as well as by other examples, the correctness of the view so steadily gaining ground that pulmonary phthisis is contagious. According to him "tuberculosis is *always* due to contagion, and that no one becomes tuberculous unless he receives from the exterior the germ of the malady, the bacillus of tuberculosis." The lecture was published in the *Semaine Médicale*, whereupon Dr. Henry Bennet, whose name is so intimately connected with the subject of phthisis, endeavored to refute the conclusions of Dr. Debove as being too positive, and pointed out the dangerous consequences of such a theory, which, if true, the disease would be worse than the plague, and each tuberculous patient would have to be treated like the lepers of old, that is, he would have to be completely isolated from the rest of the world to prevent contagion. Social intercourse would be simply impossible and the inconveniences to the individual himself and the risks of his presence anywhere would be so great that it would be as logically a charity, almost a duty to kill him as would be done with animals affected with rinderpest. Fortunately, however, adds Dr. Bennet, clinical experience proves that such a doctrine is

absolutely false. According to his own personal experience, extending to nearly half a century, during twenty-four years of which period he has had almost unprecedented opportunities of observing the malady in all its phases, he is forced to the conclusion that Dr. Debove simply misinterpreted the cases that came under his notice. The subject of the contagiousness of pulmonary phthisis was also fully discussed last winter by the Medical Society of Mentone, of which Dr. Bennet was President, and the members unanimously concluded that, admitting the possibility of the contagion of tuberculosis, it was so only in exceptional cases and under very special circumstances. That there was no danger of living with tuberculous patients even in the same room, provided the latter be well ventilated, but a person in health should on no account sleep in the same bed with a consumptive patient.

A league against vivisection is being organized in Paris, of which Victor Hugo has been elected Honorary President. The society, at present, is composed principally of ladies, newspaper writers, and literary characters, and the list of the members which has as yet been published is not a very long one.

Two new asylums for rickety and otherwise deformed children are to be established in the most populous districts of Paris, under the patronage of the Municipal Council. These institutions, which are to be designated "Écoles-dispensaires," will partake of the character of an infirmary and a school where the children will have the medical or surgical attendance required by their condition, and at the same time receive the education suited to their age and mental capacity.

The ambulance scheme for street accidents, submitted more than two years ago by Dr. Nachtel to the municipal authorities of Paris, has only now received official sanction. The entire plan proposed by Dr. Nachtel is to be carried out, but it will perhaps take three years at least before we see anything of it.

Long ere this reaches you the Count de Chambord, one of the noblest princes that ever lived, will perhaps be no more. His malady seems to be of such a complex nature as to defy the diagnostic powers of such men as Billroth, Dratsche, and Bamberger, who have been summoned to Frohsdorf, the Count's residence, to meet the regular medical attendant, Dr. Meyer, in consultation. Although they have been more than a week in attendance, they are not yet fixed as to the precise seat or nature of the malady before them. The seat, however, is said to be in the gastric region, where a tumor is felt, but the nature of the latter has not yet been ascertained. But, judging from the symptoms present: inappetence, frequent vomiting, and rapid emaciation, the tumor is evidently of a malignant character. This opinion has been emitted by the consultants, but they still hesitate between cancer and simple abscess, and even retrocedent gout has been mentioned in the nomenclature of the diseases from which the illustrious patient is said to be suffering. The medical men are, however, agreed as to the extreme gravity of the case, and everything seems to portend a fatal issue, the accomplishment of which is only a question of a few days, or, perhaps, only hours. The medical men in attendance are all foreigners, and it has been remarked that no physician or surgeon has been summoned from Paris.

[According to a cable despatch, Professor Vulpian has examined the distinguished patient and has failed to find any tumor.—Ed.]

AMERICAN HOSPITALS.—M. Poncet, in *Lyon Medical*, says "that nowhere has he seen in Europe a finer outfit than that of the New York Hospital and the Boston City Hospital. If no country can compare with France in ease and comfort, it is nevertheless true that in relation to certain hygienic conditions we ought to imitate what is done elsewhere, and especially in America."

Reports of Societies.

AMERICAN OTOLOGICAL SOCIETY.

Sixteenth Annual Meeting, held at Hotel Kaaterskill, Catskill Mountains, July 17, 1883.

MORNING SESSION.

THE Society was called to order at 10.30 A.M., by DR. J. S. PROUT, of Brooklyn, N. Y., Vice-President, the President, Dr. J. Orne Green, of Boston, Mass., being absent on account of sickness in his family.

Business Committee—Drs. E. Dyer, of Pittsburg, Pa.; E. W. Bartlett, of Milwaukee, Wis., and F. B. Loring, of Washington, D. C.

Committee on Membership—Dr. E. Dyer was added *pro tem.* to this committee, because of the absence of Dr. H. G. Miller, of Providence, R. I.

The Treasurer, DR. J. Y. B. VERMYNE, of New Bedford, Mass., read his report, which was referred to Dr. G. Strawbridge, of Philadelphia, for auditing, who subsequently reported that the accounts were correct.

DR. BARTLETT, Chairman of the Business Committee, announced the bulletin. The first paper was read by DR. W. W. SEELY, of Cincinnati, O., entitled

A CASE OF PRIMARY EPITHELIOMA OF THE AURICLE.—REMOVAL OF THE ENTIRE AURICLE BY THERMO-CAUTERY.

The patient was a male, sixty years of age, who, six years ago, was bitten on the ear by a rat. The wound never healed, but finally developed the growth removed. During the last year it had increased in size rapidly and bled easily on irritation. The original wound was near the summit of the helix. The tumor was removed by means of the thermo-cautery, the hemorrhage being only slight. The entire surface of the stump was covered with a thick layer of powdered boracic acid, and the patient was sent home within five weeks with a perfect scar. Dr. Seely regarded primary epithelioma of the auricle as rather rare. Although in this case the thermo-cautery acted well, he thought that the knife with torsion of the arteries was a preferable method. He also believed that under the boracic acid treatment the healing period of the wound was reduced at least one-half.

DR. KNAPP, of New York, thought it rare for epithelioma to arise from trauma.

DR. SEELY thought it generally accepted that epithelioma might be due to trauma, and asked what Dr. Knapp would regard as the cause in cases of epithelioma of the lip supposed to be due to using clay-pipes, etc. *

DR. KNAPP said that the pipe might produce constant irritation of the lip, but he thought that it was not exactly traumatism.

DR. SEELY regarded it as the perfection of trauma. The special point of interest in his specimen was its occurrence in a region where neither traumatism nor epithelioma is likely to develop.

INVITED GUESTS.

DR. STRAWBRIDGE, of Philadelphia, introduced Drs. Andrews and L. Webster Fox, of Philadelphia, and they were invited to attend the meetings of the Society.

A paper "On the Intermittent Perception of Sound, as Conveyed through the Air and the Cranial Bones, with a Brief Summary of the Results of Treatment in Chronic Aural Affections with Impaired Hearing," by DR. J. A. ANDREWS, of Clifton, Staten Island, was read by title and referred to the Committee on Publication.

Dr. Andrews then read a paper on

THE RECOGNITION OF BRAIN COMPLICATION IN AURAL AFFECTIONS,

which contained the clinical histories, together with the record of five autopsies, after death from brain disease

secondary to ear disease, under his own observation. Special attention was directed to the condition of the eye, and in all his cases the ophthalmoscope revealed either papillitis or a hazy, slight cedematous appearance of the optic-nerve disk, very valuable corroborative evidence of a cerebral complication, especially where the other symptoms were obscure. Dr. Andrews believed that most ophthalmologists would endorse the statement that optic neuritis and central vision of $\frac{2}{3}$ were not incompatible. The existence of a cloudy disk in cases of ear disease should excite suspicion, and he believed that the condition of the optic-nerve disk furnished evidence which has not received the attention it deserves. In the majority of reported cases the condition of the eye is only incidentally referred to. In one case there was a cerebral abscess which Dr. Andrews thought had undoubtedly existed for twelve years. It was also a significant fact, in connection with cerebral localization, that abscess secondary to ear disease is usually in the medullary substance and seldom in the cortex. The significance of special symptoms, as vertigo, vomiting, headache, more continuous and less paroxysmal than with brain tumor, edema over the mastoid, etc., were considered. Fever was very often absent. The sight was most affected on the side of the brain lesion.

DR. KIPP, of Newark, N. J., had published a number of cases in which eye-symptoms were present, and also stated that Dr. Knapp had since published several. Dr. Kipp's published cases preceded those reported by Zaufel.

DR. SEELY, of Cincinnati, had examined the eyes with the ophthalmoscope in cases of suppurative middle-ear disease, but so far with negative results, and he thought that definite results had not yet been obtained in that direction.

DR. STRAWBRIDGE, of Philadelphia, said that after Dr. Roosa directed attention to this subject at the last meeting, held at Newport, he had examined the eyes of all his patients suffering from suppurative middle-ear disease, but without satisfactory results. He had also made an analysis of the urine and had frequently found large quantities of albumen present when brain complication existed.

DR. KIPP said he had continued his observations and had found, in cases in which meningitis is present, that there was almost always a change in the fundus something like optic neuritis; something between edema and actual inflammation of the nerve. The change had been claimed only for those cases in which cerebral complications existed.

DR. ANDREWS said he alluded only to those cases in which brain complications were suspected. In all his reported cases he had examined the urine with negative results.

DR. SEELY did not doubt that, in cases of actual brain complication, more or less evidence would be found in the fundus oculi, but in such cases the ocular symptoms are less important than in those where the question of diagnosis is doubtful, or in the cases of suppurative middle-ear disease as they are generally seen. He had seen two or three cases in which there were marked changes in the eye on the side of the affected ear, but these passed away and he was left in doubt whether there was very much affection of the brain.

DR. KIPP believed that optic neuritis might exist with ear trouble and pass away as the cerebral affection ceased.

DR. BARTLETT, of Milwaukee, regarded ophthalmoscopic examination as very valuable in the acute stage of meningitis. A slight cloudiness of the fundus indicated that degeneration of the parts of the brain involved has not yet taken place, but when the degeneration has begun the appearances in the eye disappeared, sight improved, etc. For the alienist, therefore, such examinations were important.

DR. SEXTON, of New York, asked if the ophthalmoscope had been found of service as a means of diagnosis

where other symptoms have not been prominently observed, especially in fatal cases of meningitis and cerebral abscess.

DR. KIPP had examined many hundreds of cases of otitis media, and had not found any cases with eye symptoms in which there were not other symptoms of brain complication.

DR. KNAPP thought that the ophthalmoscope sometimes gave most valuable evidence, more so than could be obtained from the patient. In one of his published cases the œdema was very slight, while the pain and other subjective symptoms were marked and had existed for some time; but as soon as the symptoms became severe and pointed toward a fatal termination, the optic disk was swollen first upon one side and then upon the other. The recession of the ocular appearances had guided him with regard to allowing the opening made in the mastoid to close, and in just these cases ophthalmoscopic examination had been of great value. When the optic disk gets normal, and the discharge from the mastoid is slight, he thought the opening could with safety be left to close, and he thought he had, in this way, abridged the period of healing materially.

The paper was further discussed by Drs. Sexton, Strawbridge, Seely, Knapp, and Kipp.

A paper by DR. SEXTON, of New York, entitled "External and Internal Inflammation of the Mastoid, with Cases," was read by title and referred to the Committee on Publication.

DR. READ J. MCKAY, of Wilmington, Del., then reported a case of

ACUTE DESQUAMATIVE INFLAMMATION OF THE EXTERNAL AUDITORY CANAL—ACUTE OTITIS MEDIA—MASTOIDITIS AND CHRONIC MENINGITIS—RECOVERY.

DR. CHARLES H. BURNETT, of Philadelphia, read a paper entitled

A CASE OF MASTOID DISEASE—ARTIFICIAL PERFORATION OF THE BONE—TEMPORARY RELIEF—DEATH FROM PYÆMIA.

The paper contained an account of a case of chronic purulent inflammation of the middle ear inducing general increased vascularity of the pyramidal part of temporal bone, hyperostosis of the outer wall of the mastoid groove without necrosis. The mastoid cavity became filled with cheesy debris, and this furnishing a pyæmic source of embolism, was followed by embolism of a chronic form, as shown first by abscesses in the lung and then by infiltration of the liver with abscesses.

Dr. Burnett also expressed the opinion that the operation of trephining the bone is comparatively unattended with danger, and affords the one slim chance of escape from death in cases of true mastoid disease, which must necessarily furnish an embolic source for the products of inflammation, purulent, and cheesy debris pent up in the mastoid cavity. In such cases there are the chances of death from embolism, while there are none from the operation. In the case reported by Dr. Burnett, the patient survived the mastoid operation two weeks, and the wound nearly healed, when the man was seized with a chill and rapidly sank from embolic hepatitis.

These papers gave rise to an extended discussion concerning trephining the mastoid when involved as a complication in middle-ear disease.

DR. STRAWBRIDGE, of Philadelphia, had never performed the operation upon the living subject. He had seen about five thousand cases of purulent middle-ear disease during the last twelve years, and had not had occasion to trephine a single mastoid. Nor had he had but a single death, which occurred in a child six months old, that died a few hours after he first saw the case. In studying the subject he had been struck with the very small percentage of cases in which pus was found after the bone had been trephined. He would like to ask if the absence of pus was not evidence that the operation had not been indicated.

DR. KNAPP, of New York, said that the mastoid had been trephined with marked benefit in quite a number of cases in which pus was not found. Such cases had been reported by Hartmann and also by himself. His firm conviction was that, when chronic middle-ear disease, even without suppuration or perforation, was attended with more or less obstinate constant pain which has its origin in the mastoid process and radiates from there over the corresponding half of the face and side of the head, trephining the mastoid is indicated.

DR. SEXTON, of New York, had not seen so many cases requiring opening of the mastoid as had been mentioned by several authorities, as Buck, Schwartze, and others, and only a very few in which he had thought the operation might be necessary, without some further evidence than the pain in the mastoid. He thought there might be danger in attributing too much importance to pain as a symptom in these cases. With regard to operative procedure it had occurred to him to have the opportunity to liberate the pent-up secretion through the posterior wall of the auditory canal, and he thought that, in a large majority of cases, pointing takes place in that direction rather than toward the brain. He regarded early constitutional treatment as especially important, particularly by the use of the sulphide of calcium, of which he seldom, of late, had given more than one-tenth of a grain at a dose, and frequently a much smaller quantity, repeating it perhaps every one or two hours. Of course the liberation of pus when formed was a well-established surgical procedure and must not be ignored.

DR. THEOBALD, of Baltimore, said that his experience had been similar to Dr. Strawbridge's, and so far he had opened the mastoid only upon the dead subject. He did not believe that the indications for performing this operation occurred very frequently. Early constitutional and local treatment he thought would have cured most of the cases in which the mastoid had been opened. He regarded leeches as exceedingly serviceable.

DR. KIPP, of Newark, N. J., thought that the operation was essentially harmless, and believed it to be better to operate and not find pus than to allow the case to go on and the patient die with pus in the mastoid cells where by an operation it could have been removed. He maintained that there were cases in which suppuration occurred in the mastoid, irrespective of constitutional treatment.

DR. BARTLETT, of Milwaukee, had not found it necessary to trephine the mastoid. He had relied on poultices applied every half hour, as hot as the patient can bear, and had seen several cases in which pointing took place within twelve hours, and the pus was then let out with an ordinary scalpel, cutting through into the mastoid.

DR. STRAWBRIDGE corroborated Dr. Bartlett's experience concerning the value of poultices.

DR. BURNETT thought that poulticing could not produce much effect upon the mastoid cells if the external wall of the process is intact.

DR. JONES, of Chicago, thought no general rule could be laid down, but that each case must be treated independently, according to conditions present.

DR. E. E. HOLT, of Portland, Me., had had forty cases of mastoid disease in two thousand cases of ear disease of all kinds. He had not perforated the mastoid, and had not had but three deaths, all of which could be explained without reference to the condition of the mastoid. He had used leeches more than any other measure, unless it was incision.

The subject was further discussed by Drs. Sexton, Burnett, and Knapp.

DR. E. E. HOLT, of Portland, Me., then read a paper in which he reported a case of

TERATOID TUMOR OF BOTH AURICLES,

having a clinical history of recurrent fibroid. The patient was a woman, twenty-nine years of age, of light complexion and good average health. These morbid

growths were of unusual interest in the following respects : 1. they promptly followed perforation of the lobe and wearing of gold ear-rings ; 2. they have repeatedly occurred during a period extending over twenty years ; 3. they have undergone remarkable change in structure. In proof of this latter assertion a portion of a letter was read from Dr. John H. Ripley, of New York, who had removed the tumors several times, and who stated that they contained nothing but dense interlacing fibrous tissue. An exhaustive examination of the recent growths, by Dr. Edward Preble, of Portland, Me., determined, however, that the said tumor contained germinal matter in abundance with the following tissues, namely : myxomatous and adenoid tissue, giant cells, fibro-plastic tissue, loose areolar tissue with infiltrated fat, innumerable elastic fibres, fine and coarse fibrous tissue, hyaline reticular and fibro-cartilage, smooth muscle, fragments of large blood-vessels, well-developed skin with corium, papillae, rete mucosum and epidermis, hair-follicles, hair and sebaceous glands, together with certain unclassifiable structures.

Drs. E. D. Spier, of Brooklyn, and John Van Duyn, of Syracuse, N. Y., were

PROPOSED FOR MEMBERSHIP,

after which the Society adjourned to meet at 7.30 P.M.

EVENING SESSION.

The Society was called to order by the Vice-President, Dr. J. S. PROUT.

Drs. L. Webster Fox, of Philadelphia, and Swann M. Burnett, of Washington, D. C., were

PROPOSED FOR MEMBERSHIP.

Drs. Murdoch, of Baltimore ; Williams, of Boston ; and R. H. Johnson, of Philadelphia, were introduced and invited to remain in attendance.

AMENDMENT TO THE BY-LAWS.

DR. JOHN GREEN, Chairman of the Committee on Membership, offered the following : The first by-law, relating to the election of members, shall be amended so as to read "after the report of this committee has been received, and *at the same meeting*," etc.

DR. SEXTON, of New York, presented a patient who had formerly been under his care for

CHRONIC INFLAMMATION OF THE MASTOID CELLS WITHOUT PERFORATION OF THE MEMBRANA TYMPANI.

When under his treatment the case was complicated with ozena.

This case opened the discussion again on the question of trephining the mastoid, which was participated in by Dr. Gruening, of New York, who argued very strongly in favor of the operation, Drs. Kipp, Bartlett, Theobald, Burnett, Sexton, and Webster.

DR. E. E. HOLT, of Portland, Me., then read a paper entitled

OBSERVATIONS ON THE HEARING POWER IN DIFFERENT CONDITIONS,

in which was given the results of examination of four series of cases : 1, twenty-four cases of chronic non-suppurative otitis media from private practice ; 2, twenty-four machinists ; 3, twenty-four boiler-makers ; and 4, twenty-four persons with normal ears.

The hearing power was tested by the voice, tick of a stop-watch, tuning-fork, and Koenig's rods. and the average age ratio of bone to aerial conduction and the audibility of Koenig's rods in three series of tests were compared with each other and with the normal ear. It was ascertained that the ratio between bone and aerial conduction diminishes in a corresponding degree to that of the hearing power for the voice, and that the average audibility for the upper limit of Koenig's rods was quite equal to the average normal of 40,000 V. S., as deter-

mined by Dr. Blake ; therefore the conclusion was drawn that the loss of hearing in the machinists and boiler-makers was due much more to a defect in the conducting than in the perceptive part of the organ of hearing for the following reasons : 1. Because of history or present condition of catarrh of the middle ear and naso-pharynx. 2. Because the tuning-fork when placed vibrating in the centre of the teeth, was heard louder and longer in the more affected ear, and the sound of it was invariably increased by pressing on the tragus and closing the meatus. 3. Because, had there been any considerable disease of the labyrinth, they would not have responded so nearly to the normal average audibility for the upper limit of Koenig's rods, since such an astute observer as Dr. Blake, who has made extensive use of them, has never had a case of labyrinth disease without a "*marked loss of hearing*" for the Koenig's rods."

In regard to hearing in a noise, several of the three series of persons made a voluntary statement that they could not hear better in a noise. These were carefully tested in a quiet place and then in a noise, and in every instance there was no improvement of hearing in the noise ; on the other hand, when the voice was used at the same time it was not heard quite as well in the noise as in a quiet place.

DR. KIPP, of Newark, N. J., read a paper entitled

ON THE ASSOCIATION OF AURAL DISEASE WITH SIMPLE SPARKLING SYNCHISIS OF THE VITREOUS HUMOR.

In six of the seven cases of synchysis of which he has record aural symptoms were present ; in the seventh case it is not known whether or not ear trouble existed. In five of the cases the synchysis scintillans existed in only one eye, and in two of these the ear of the same side only was affected ; in the other three both ears were diseased. In four of the cases the ear-trouble was probably situated in both the middle ear and the nervous apparatus. In one case there was chronic suppuration of the middle ear, which had been preceded for years by impairment of hearing without otorrhoea. In the sixth case there was absolute deafness of the one ear since infancy. Otological literature contains no record of similar cases, and the author thinks that the association of the two affections in his cases may have been merely accidental. They are published with a view of inducing others to examine their cases of synchysis for aural trouble, and thus settle the question.

The paper was discussed by Dr. W. S. Little, of Philadelphia, and Dr. Webster, of New York.

A paper by DR. CHARLES A. TODD, of St. Louis, on "Anomalous Sebaceous Gland in Immediate Proximity to the Auricle," was read by title and referred to the Committee on Publication.

DR. SEXTON, of New York, then read a paper (see p. 90) on

THE SIGNIFICANCE OF THE TRANSMISSION OF SOUND TO THE EAR THROUGH THE TISSUES IN AURAL DISEASE.

It was discussed by Drs. Burnett, Holt, Andrews, and Kipp.

DR. SEXTON then exhibited fourteen photographs of various forms of ear affections ; also two ear-syringes, together with a *hooked curette* for removing foreign bodies from the ear, where it is necessary to use forceps.

DR. H. KNAPP, of New York, read a paper on

OBSTINATE PURULENT DESQUAMATIVE OTITIS MEDIA,

in which he reported a case that was finally cured. He laid special stress upon the fact that when there is desquamative otitis media palliative treatment produces only temporary benefit, and that to effect a cure it must be converted into an acute case that will produce a condition that can be cured. The case was a new confirmation of views which he expressed before the Society two years ago concerning the treatment of granulations and polypi. He then stated that in cases of diffuse

granulations, and broad sessile polypoid excrescences he abstained from destroying them by caustics or sharp instruments, because these procedures are likely to destroy essential parts of the drum-cavity, and terminate in replacing the mucous membrane by cicatricial tissue, thus bringing about an unpleasant condition known as sclerosis. The only reasonable plan is to change the condition of the parts, and this he accomplishes by instillations of warm water and keeping the parts moist by applying cotton steeped in glycerine. A somewhat prolonged discussion followed on the question whether or not a new drumhead is ever actually formed after being destroyed by disease.

The Society then went into executive session, and afterward adjourned to meet in 1884.

New Members—Dr. W. S. Little, of Philadelphia; Dr. B. E. Fryer, U.S.A., Fort Leavenworth, Ks.; Dr. R. O. Born, of New York; and Dr. J. A. Lippincott, of Pittsburgh, Pa.

President—Dr. Charles H. Burnett, of Philadelphia, Pa.; *Vice-President*—Dr. J. S. Prout, of Brooklyn, N. Y.; *Secretary and Treasurer*—Dr. J. J. B. Vermeyne, of New Bedford, Mass.; *Committee on Membership*—Drs. John Green, of St. Louis, Mo.; H. G. Miller, of Providence, R. I., and A. Matthewson, of Brooklyn, N. Y.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at Kaaterskill, N. Y., July 18 and 19, 1883.

WEDNESDAY, JULY 18—FIRST DAY—MORNING SESSION.

THE Society was called to order at 10 A.M. by the President, DR. HENRY D. NOYES, of New York, who made a few congratulatory remarks and then appointed the following committees:

Committee on Bulletin.—Drs. F. B. Loring, of Washington, and E. W. Bartlett, of Milwaukee.

Business Committee.—Drs. John Green, of St. Louis; E. Gruening, of New York; O. F. Wadsworth, of Boston; S. Theobald, of Baltimore, and E. Dyer, of Newport.

The Treasurer's report was read and referred to Dr. David Webster, of New York, who subsequently reported that all the accounts were correct. The report was adopted.

CANDIDATES FOR MEMBERSHIP.

The following were nominated: Drs. Charles S. Turnbull, of Philadelphia; Miles Standish, of Boston; J. L. Thompson, of Indianapolis; W. T. Bacon, of Hartford; Stephen O. Ritchie, of Washington, and John Van Duyn, of Syracuse.

NEW MEMBERS.

The following were elected: Drs. B. E. Fryer, U. S. A., of Fort Leavenworth, Ks.; J. A. Andrews, of Clifton, Staten Island; L. Webster Fox, of Philadelphia; J. A. Lippincott, of Pittsburgh; J. L. Minor, of New York; and E. E. Holt, of Portland, Maine.

INVITED GUESTS.

The following were invited to attend the sessions of the society: Drs. T. Y. Sutphen, of Newark, N. J.; R. H. Johnson, of Philadelphia; Miles Standish, of Boston, and Swann M. Burnett, of Washington.

The Secretary, DR. R. H. DERBY, of New York, read the *resignation* of Dr. Thomas J. Morton, of Philadelphia, which was accepted.

INFLUENCE ON REFRACTION OF FOUR YEARS OF COLLEGE LIFE; ILLUSTRATED BY STATISTICS OF THE LAST FOUR CLASSES GRADUATED FROM AMHERST COLLEGE.

A paper on the above subject, sent by DR. HASKET DERBY, of Boston, was read by Dr. Miles Standish, of Boston.

The author had been able in 254 instances to trace the refraction through the whole term of four years. The examinations were all personally conducted with glasses, and in the majority of cases, certainly in all doubtful ones, with the ophthalmoscope. The results given are those obtained by glasses. The use of atropine was entirely impracticable, as the students could not have been allowed even temporarily to be disabled from the active prosecution of their studies. Dr. Derby followed the example of Emmet and Loring in stating degrees of ametropia as slight as O. 5 D., and included nothing less. The average age of those examined was at entrance 19 years, at graduation 23. The number of cases was small, it is true, but it is one of the few attempts yet recorded to trace the movement of refraction among the more highly educated during this particular period of life and for a continuous term of years.

The general results were, hypermetropia at entrance, 39, at graduation, 47; myopia at entrance, 90, at graduation, 120; emmetropia at entrance, 125, at graduation, 87.

Analyzing the ametropia he found under the head of manifest hypermetropia, of which there were 39 cases at entrance, 1 changed to myopia, 2 diminished, 27 remained stationary, and 9 increased in amount.

Of the myopia there were 90 cases; 32 remained stationary, 58 increased in amount.

The observations concerning emmetropia possessed peculiar interest, the results somewhat militating against theories that have found general acceptance. There were at the time of entrance 125 cases of emmetropia. Of these 86 remained emmetropic, 10 developed hypermetropia, and 29 developed myopia. The average age of those thus developing myopia was very nearly nineteen at entrance, twenty-three at graduation. The average myopia developed amounted to nearly 1 D. (0.982).

So far as these figures go they tend to show, first, a large amount of myopia, even in this country among the educated classes. The author said it was difficult to compare Dr. Loring's figures with his own, because Dr. L.'s statistics were based upon observations made between the ages of six and twenty-one, and his observations were made between the ages of eighteen and twenty-three. But all researches at the latter age go to prove that one-half, or very nearly, of the educated community is myopic in this as well as in other countries. Moreover, contrary to the impressions so long entertained, myopia may be acquired at or near twenty years from the same causes that produce it at an earlier age, and it may continue to progress until the course of study is completed.

The paper was discussed by Drs. Webster and Mitten-dorf, of New York; Gruening, of New York (who directed special attention to the use of the term dioptric, urging that some uniform mode of spelling be adopted); Carnalt, of New Haven; Little, of Philadelphia, and Hutchinson, of Utica.

SOME IMPROVEMENTS IN INSTRUMENTS AND APPLIANCES FOR CATARACT OPERATIONS.

DR. RUSSELL MURDOCH, of Baltimore, read a paper with the above title. He exhibited an ophthalmostat, or a self-holding eye-forceps, and an eye-speculum, which were modified from those exhibited to the Society in 1874. The distinguishing features of the speculum were "absence of spring and set screw." The change in the ophthalmostat was such that it seized the conjunctiva in a vertical fold, and rotated the eyeball without dragging it, and the substitution of three little hooks for one pair, which secured greater steadiness.

The new instruments consisted, first, in the combination of Graefe's knife, end to end, with Wecker's scissors. Second, a combination of iris forceps with the cystotome and shell spoon. The advantages claimed for these instruments were that an assistant is dispensed with,

and that seven instruments are reduced to three in performing the modified linear extraction of cataract.

Dr. Murdoch also exhibited a bandage which could be quickly made and easily applied.

Dr. GRUENING, of New York, thought that outside of the limits of civilization such complicated instruments might be useful, but that within the limits they should be discarded entirely, and that a cataract operation should not be undertaken without an assistant. Concerning the bandage, he said, an ordinary flannel bandage could not be replaced by anything which had yet been brought forward. No bandage can produce the pressure that can be applied by the use of the flannel roller. It is necessary to immobilize the eye, and this cannot be done by any substitute for the ordinary flannel bandage.

THE PRESIDENT remarked that he had had some experience in the use of the little forceps in fixation, and had long ago discarded the instrument, because it did not give so much control over the eye as one might imagine. He had reached the conclusion that the operator's hand should guide the forceps.

Dr. MURDOCH remarked that he was well aware the gentlemen in New York could obtain an assistant at any time, but he thought there were occasions outside where it was impossible to secure an assistant, and that the instrument had been devised especially to meet such emergencies.

Dr. THEOBALD, of Baltimore, believed that the eye could not be immobilized by any bandage whatever which was at all permissible, and that there was a decided objection to the long flannel bandage, especially during hot weather.

Dr. GRUENING said he would not insist upon the flannel bandage, but that he would insist upon the long bandage, and of late he had used gauze, dipping it into water before applying it. He believed that the eye could be perfectly immobilized if the bandage were properly applied. The first thing to be done is to fill up the orbital depression, so that when the hand is placed over it the brow and the bridge of the nose are not felt, but that the hand rests entirely upon the pad, and upon that pad pressure with the bandage can be made which will render the eye entirely immobile.

Dr. THEOBALD thought if Dr. Gruening would apply the bandage in the manner described to his own eye he would find that the eyeball had not been rendered immobile.

Dr. HENRY S. SCHELL, of Philadelphia, reported a case of

TUBERCLE OF THE IRIS.

The patient was a boy nine years of age, who applied for treatment at the Will's Eye Hospital, August 29, 1881. The left eye had been painful for four days, and exhibited the general signs of ordinary plastic iritis. Atropine and mercurial ointment were prescribed. On the 16th of September no effect had been produced by the treatment. In the latter part of October the boy came to the Children's Hospital suffering from well-marked coxalgia in the second stage. There was a distinct history of phthisis on the mother's side. The left eye was still somewhat painful. The pupil was immobile, and there was a ring of circumscribed injection, and projecting from the nasal side of the pupillary margin was a small yellowish-white nodule the size of a pin's head and tinged with pink. This nodule gradually increased in size. The hip-joint disease progressed. The eye was enucleated, and was examined by Dr. G. B. Lawrason, of New Orleans, who reported that it consisted of two or three tubercular masses embedded in inflammatory product. The tubercles seemed to have developed in the organized inflammatory product, which nearly filled the anterior and posterior chambers.

THE PRESIDENT said that within the last year a case had been under observation in New York which illustrated the difficulties in diagnosis. The patient was four

years of age, and the gross appearances presented by the eye were absolutely indistinguishable from a glaucomatous condition or a metastatic choroiditis. The patient continued under observation for several weeks without much progress in the disease. The eye was then enucleated, and tubercular disease was found to be the true nature of the lesion. It was felt at the time by those who examined the patient that, in some cases, the differential diagnosis between glaucoma and tubercular disease is impossible.

TUBERCULOSIS OF THE CILIARY MUSCLE AND IRIS.

Dr. O. F. WADSWORTH, of Boston, reported a case of the above character occurring in a girl three and a half years old. Dr. Hasket Derby, of Boston, saw the patient when the process had lasted two weeks, and regarded it as a case of kerato-iritis. The pupil contracted and remained so in spite of atropia; the cornea was hazy; the lids were natural. Afterward, when Dr. Wadsworth saw the patient the cornea was hazy, the conjunctiva was moderately congested, there was no marked ciliary congestion, there was good anterior chamber, and the pupil was of good size. The patient died about six months afterward. The eye after it was removed contained a mass about six millimetres in thickness. The vitreous was replaced by serous fluid, there was nothing of the lens to be seen. The iris and choroid were in place and behind the mass. Microscopical examination, made by Dr. Ernst, of Boston, revealed that the growth was tubercular in character, and he was also able to demonstrate the presence of bacilli. There was no evidence of pulmonary disease. It was learned late in the history of the case that the father and the father's brother died of phthisis, and that other members of the family were subject to bronchial attacks, so called.

The paper was discussed by Drs. Prout, of Brooklyn, and Webster, of New York.

Dr. S. F. MCFARLAND, of Oxford, N. Y., read a paper which contained

A PERSONAL EXPERIENCE WITH PRISMATIC GLASSES.

During his boyhood he had a slight divergence, occurring and disappearing at times, although seldom sufficient to attract attention. Still he had the full use of his eyes, could judge of distance as well as others, and was even expert in the sports of youth requiring binocular vision. He had no inconvenience during his studies, always enjoying the greatest comfort during the most severe and protracted application. During the autumn of 1862 he contracted typho-malarial fever in the army, and after recovering from this he found that he had lost the full and comfortable use of his eyes, which continued with the usual pain and annoyance attending a futile effort to use both eyes in conjunction, and he was compelled finally to discontinue reading almost entirely until in January, 1866, he consulted Dr. H. D. Noyes, who gave him plain prisms of seven degrees each, bases inward, for distance, and eight degrees each with plus thirty-six spherical for reading. At that time he had been nearly three years unable to obtain binocular vision even for a moment, but at once he was able to see distinctly. He has never discontinued their use, they have been varied from time to time, but he has always adhered to the prisms. He suffers the inconvenience that he cannot maintain continued binocular vision, but can obtain and retain it long enough for an iridectomy, or the extraction of a cataract, and even during very protracted operations, although at the expense of pain and very distressing lassitude following the effort. Without the prism he could not do these things, inasmuch as slight differences in distance would not be appreciable. With bifocal sphero-prismatic glasses he is able to do all his office work without changing, and with a reasonable amount of comfort.

Dr. R. J. McKAY, of Wilmington, Del., said that a music teacher came to him in September, 1879, who, while standing directly in front of his class and moving

his eyes from right to left extremely without moving his body, weakened the external recti. Dr. McKay ordered prisms with the bases external, which the patient had worn ever since with comfort for distance only.

DR. O. F. WADSWORTH, of Boston, then read a paper ON THE APPARENT CURVATURE OF SURFACE PRODUCED BY PRISMS.

The phenomenon is very familiar that when we look through prisms with the bases inward, with a plane surface, the surface appears convex, and with the bases outward the surface appears concave. He had not met with any exception to this phenomenon, and the communication was intended to explain it, and was the theory which had been worked out by Dr. Pierce. It was illustrated with diagrams.

DR. S. W. BURNETT, of Washington, on invitation, presented a specimen of

TUBERCLE OF THE CHOROID,

accompanied with the clinical history of the case, which occurred in a colored girl fifteen years of age.

DR. J. A. SPAULDING, of Portland, Me., then read a paper in which he reported a case of

SYMPATHETIC NEURO-RETINITIS.

The author first referred to the able works of Mauthner and Kneis, whose views are so diametrically opposed, the latter believing that the so-called cases of sympathetic neuro-retinitis are open widely to criticism. It seemed desirable, therefore, to publish, and thus to offer to careful criticism, every case of apparent sympathetic inflammation of the retina and optic nerve (either alone or conjoined), and above all does this appear necessary when we have, as at present, to offer one in which so far as accurate and repeated examinations have availed, the retina and optic papilla of one eye underwent inflammation after an injury to its mate, while at no time from the beginning of the case were there ever any visible signs of inflammation of any portion of the uveal tract. The patient was a Danish woman, fifty-six years of age, and healthy in every respect. On January 6, 1883, she was struck in the eye by the horn of a cow, which rendered her at once and forever totally blind in that eye. The patient saw a flash of light and then the sight was gone. Eleven weeks after the injury to the right eye the patient, much reduced in health on account of the pain and irritation in the right eye and its neighborhood, came to Dr. Spaulding for consultation. On March 30th, about four weeks after first seen, the right eye was enucleated on account of the excessive pain from which the patient was suffering. The operation was followed by excessive hemorrhage, which could not be checked by pressure or hot water, and only ceased after ligature of the artery deep in the orbit, and of a second one which appeared to spring from a band of connective tissue uniting the globe and upper eyelid. The case subsequently progressed favorably, and the patient was sent home. No medicinal treatment was adopted. The result appears to justify the opinion of the truly sympathetic nature of the neuro-retinitis in the left eye, for the sight gradually returned to the remaining eye. The pain in the head disappeared with considerable rapidity. July 14, 1883, examination with the ophthalmoscope revealed normal left eye, vision $\frac{3}{8}$. The enucleated eye was lost. The presence of this neuro-retinitis with total loss of vision in the eye five weeks after an injury to the other, and without any other visible or possible cause, such as idiopathic iritis, syphilis, cerebral lesion, etc., indicates the sympathetic nature of the disease. Iritis was excluded in any form as the possible cause of the difficulty in the left eye.

DR. WEBSTER, of New York, said he had reported two cases of sympathetic neuro-retinitis in which he enucleated the eye giving rise to the trouble and with excellent results. The neuro-retinitis subsided, and the eye re-

covered with much better vision than existed before the operation was performed.

DR. PROUT, of Brooklyn, said, concerning the hemorrhage in Dr. Spaulding's case, that in one instance, after resorting to various methods unsuccessfully, he arrested the hemorrhage by digital pressure with the finger in the orbit.

DR. MITTENDORF, of New York, had employed sponge-pressure, that is, applying a good-sized, soft, moist sponge over the orbit, and securing it with a roller bandage after enucleation, to be worn for twenty-four hours, then changed and worn for the next twenty-four hours, and he had never experienced any trouble from hemorrhage or from infiltration of the lids or the orbital tissues.

DR. H. W. WILLIAMS, of Boston, said he had never had any difficulty in arresting hemorrhage by means of the sponge-tent, and was unable to see how it is possible for hemorrhage to go on if the orbit was properly plugged in that way. However, since he had adopted the circular suture of Bowman, he did not recollect of having had a case where it was necessary to apply the sponge-tent.

DR. PROUT thought the removal of the tent would be exceedingly painful.

DR. WILLIAMS remarked that the patients did not like it at all, but the pain could be reduced to its minimum by removing the sponge very quickly.

DR. DYER, of Newport, while in charge of an army ward, had between two hundred and twenty-five and two hundred and fifty cases of enucleation, and in not a single one did he experience any annoyance from hemorrhage. He always used a large sponge from which ice-water was gently squeezed into the orbit, rarely for more than ten minutes, and afterward applied a double thickness of linen, covering it with one thickness of bandage.

DR. GREEN, of St. Louis, referred to a case in which ice-water and digital pressure had been employed without success, and finally he tamponed the orbital cavity with a narrow strip of linen and made external pressure with a bandage, which controlled the hemorrhage. The tampon was allowed to remain twenty-four hours, when it was removed without difficulty by a process of unravelling, as it were. He subsequently learned that the patient had a hemorrhagic diathesis.

DR. KNAPP, of New York, referred to a procedure for avoiding hemorrhage after enucleation, and it was to keep close to the sclerotic. If this precaution is observed there will be very little danger from hemorrhage. The most profuse hemorrhage occurs when the optic nerve is cut, because we are likely to go into the naturally cavernous tissue of the organ, but the division can be made without undue loss of blood by pressing the speculum into the orbit and allowing the eyeball to pop out, as it were, which will facilitate the division of the nerve and removal of the ball very materially.

THE PRESIDENT had never had but one case of serious hemorrhage which required digital pressure. He had had one case of enucleation of the eyeball for a tumor in the antrum, and in which the bleeding was so profuse that it was necessary to tampon the cavity with the ordinary kite-tail tampon made of pledgets of lint. The tampon was effectual and was readily removed.

The paper was further discussed by Drs. W. W. Seely, of Cincinnati, and F. Buller, of Montreal, Canada.

DR. DAVID WEBSTER, of New York, then reported

THIRTY-FIVE CASES OF CATARACT EXTRACTION.

They included all the cases which he had had, good and bad, from the beginning, and all the operations were performed at the Manhattan Eye and Ear Hospital. A brief clinical history of several of the most interesting cases was given. Thirty-one different patients were operated upon—males, 20; females, 11. Their ages varied from thirty to eighty-three years. Under forty years of age there were 2; between forty and fifty, 3; between fifty and sixty, 9; between sixty and seventy, 9; between seventy and eighty, 6; above eighty, 2. Twenty-eight

eyes were operated upon while the patient was under ether. Of these, 23 were successes, 2 partial successes, and 3 failures. Seven eyes were operated upon without the use of an anæsthetic; 5 of these did well, and 2 were failures. The method of operating known as "Von Graefe's modified" was used in all cases in which it was practicable; where a preliminary iridectomy was done the incision for the extraction of the lens was made in the same position as in the other cases. Preliminary iridectomy was performed in 6 cases; 4 by himself, and 2 by another surgeon. In only 1 case of the 35 was there loss of vitreous, and this was the only case in which the scoop was introduced into the eye for removing the lens, and in 3 cases there was dislocation of the lens into the anterior chamber during the preliminary iridectomy. In 1 case iridodialysis was produced during the operation, and in 1 case the iris fell before the knife on account of premature escape of the aqueous, and was cut through. In all these cases in which accidents occurred during the operation the eyes recovered with good sight. In 3 cases the cornea was thin and flaccid, and became wrinkled or collapsed after evacuation of the lens. In 8 cases there was hemorrhage from the iris immediately following the iridectomy. In 4 cases a considerable quantity of soft lens matter was left in the eye. In 1 case some inflammatory reaction was noted during recovery; this eye did well. In 4 cases there was iritis. Sloughing of the cornea occurred in 1 case, panophthalmitis in 2 cases, and in 1 there was irido-cyclitis with sympathetic inflammation of the fellow eye. A secondary iridectomy was performed in 2 cases, in both resulting in a clear pupil, but in one failing to restore sight on account of deeper disease. Keratonyxis for pupillary membranes was performed in 7 cases, and in all successfully.

The successes, taking the results of all the cases, complicated and uncomplicated, were 27; partial successes, 2; failures, 6. Dr. Webster believed, however, in justice to himself and cataract statistics, he ought to exclude the cases of extensive corneal opacity, a case of detachment of the retina, and one other case with vitreous and perhaps deeper complications. The figures would then stand: successes, 27; partial successes, 1; failures, 2. By success he meant the standard adopted by Dr. Knapp, namely $V. \frac{2}{3} \text{ or } 0.6$; partial success, ability to count fingers; failures, nothing more than perception of light.

The paper was discussed by Drs. Heyl and Strawbridge, of Philadelphia; Theobald, of Baltimore, and Carmalt, of New Haven.

DR. W. W. SEELY, of Cincinnati, then read a paper entitled

NOTES ON OCULAR THERAPEUTICS.

He directed attention, first, to the use of yellow oxide of mercury in external ocular troubles. Ten grains to the ounce of the vehicle is the best for all purposes. The less bichloride the preparation contains the less pain produced by its application. A practical point with regard to the use of yellow oxide and vaseline in conjunctival affections where there is profusion of tears, such as washes the salve out, was to substitute eserine or the bichloride in solution, to contract the blood-vessels. The strength of the bichloride solution that seems to answer every purpose is one grain to sixteen ounces of water. Such a solution is entirely painless, and has often, in his hands, set aside an acute catarrhal conjunctivitis of a violent type, after from one to three or four thorough drenchings of the conjunctiva. In corneal affections he uses a four-grain solution of eserine *once a day*, and believes that it acts altogether better than more frequent applications, either of the same or of a weaker solution. This remark applies to all classes of cases.

For the reduction of intra-ocular tension eserine has, for him, done away entirely with paracentesis.

Every one has met with cases of iritis in which atropia does not seem to act promptly and satisfactorily, possibly *because of the extreme vascularity of the iris*.

In such cases, instead of making paracentesis and extracting blood, he instils once a day a few drops of a four-grain solution of eserine. The habit of instilling eserine once a day in iritic cases has become a routine practice with him, the patient at the same time using the mydriatic in the ordinary manner. In more than one case had he seen adhesions let go after the combined use of a myotic and mydriatic that had resisted the latter alone. Iritis is the only disease in which he employs a mydriatic as a fundamental remedy.

Eserine is the remedy *par excellence* in corneal affections. In cases in which mydriasis is necessary the latter can be produced perfectly, and still the satisfactory effects of the myotic be maintained. This is illustrated in suppurative inflammation after cataract operations, formerly so unsuccessfully treated by heat and atropine.

DR. MCKAY, of Wilmington, had used yellow oxide of mercury with very favorable results in conjunctival troubles.

DR. GRUENING, of New York, said the alternate use of mydriatics and myotics for breaking up adhesions was not entirely new. He had resorted to this method as long ago as 1868. He regarded the use of eserine in iritis as an extremely dangerous practice.

DR. KNAPP, of New York, thought the alternate use of eserine and atropine was advantageous in some forms of iritis, especially the serous variety. Again, where there is increase of pressure which produces intense pain, as in certain cases of glaucoma, the pain is considerably relieved by one drop of eserine. In serous iritis the pressure is sometimes intense, and he thought that eserine could be so regulated as to prevent the noxious effects of the drug.

DR. SEELY said he did not speak of the alternate use of eserine and atropine, but wished simply to speak of the use of eserine *once a day* for the purpose of contracting the "blood-vessels," of course maintaining mydriasis by atropine. He had never seen a case in which eserine had produced iritis.

The paper was further discussed by Dr. Kipp, of Newark, Dr. Knapp and Dr. McKay.

The Society then adjourned, to meet at 8 P.M.

EVENING SESSION.

The Society was called to order by the President.

The Minutes of the Morning Session were read and approved.

DR. W. F. MITTENDORF, of New York, then read a paper on

THE TREATMENT OF DETACHMENT OF THE RETINA.

During the last three years he had treated several very extensive detachments of the retina, occurring in patients that had only one useful eye, the other being entirely blind or absent. Although no new remedy or new method had been used, it was the combination of the different plans devised for the treatment of this affection, and the mode of administering the remedies that had led to the success.

After briefly referring to the causes of detachment of the retina, the author stated that the object of the treatment must be, first, to keep the eye as free as possible from all irritating influences, which is best done by closing both eyes, or by putting the patient into a dark room; second, to keep the eye as quiet as possible, and to avoid all accommodative efforts, and for this purpose the eye must be kept under the influence of a mydriatic; third, to place the absorbents in the most favorable condition—this is accomplished by means of a pressure bandage, and he had found elastic pressure procured by means of a rubber bandage to be of the greatest assistance; fourth, to hasten the absorption of the effused fluid, if this be the cause of the detachment—this can be accomplished by the use of jaborandi or pilocarpin. He had given a hypodermic injection of one-

fourth to one-sixth of a grain of pilocarpin early in the morning, and then kept up the diaphoresis by the use of an infusion of jaborandi leaves, from forty grains to one drachm to twelve ounces of water, administered in wine-glass doses during the afternoon and evening. This treatment should be kept up for three or four weeks. He had not seen a single case in which the remedy administered in this way had to be discontinued on account of unpleasant symptoms.

If the detachment complicates a specific choroiditis, or if it follows a serous iritis demanding specific treatment, this may be used at the same time with the other remedies mentioned. In these cases the disease yields, as a rule, sooner than in other cases, and it will not be necessary to push the pilocarpin to so great an extent.

Dr. Mittendorf then reported in detail three cases, all of which were successfully treated. They tended to show: 1, that in marked detachment of the retina the energetic use of jaborandi and pilocarpin will do good, especially if the patient can be kept under the influence of the drug during the entire day and for a period ranging from twenty to thirty days; 2, that the elastic pressure bandage must be used at the same time; 3, that the patients must be kept upon the back for most of the time; and 4, that the use of atropia, which is employed without causing any inconvenience to the patient, should likewise not be neglected.

The paper was discussed by Drs. Gruening, of New York; Little, of Philadelphia; Andrews, of Clifton, Staten Island; Webster, of New York; Theobald, of Baltimore, and Spaulding, of Portland, Me., who spoke of operative treatment in these cases. He referred to a suggestion made by Mooren that an attempt be made to remove the effusion by means of the hypodermic syringe. Having a case on hand, he tried the operation. Although he succeeded in removing a considerable quantity of the subretinal effusion there was not much improvement except temporarily. He suggested that the method might be cultivated by placing a piece of rubber tubing between the needle and the tip of the nozzle, thus making an instrument somewhat similar to that used in the treatment of soft cataract. At least he thought that some form of aspiration might be made applicable in these cases.

Dr. WILLIAM S. LITTLE, of Philadelphia, then reported

TWO CASES OF CONGENITAL ECTOPIA LENTIS, ONE SYMMETRICAL, THE OTHER NON-SYMMETRICAL.

The first case occurred in a man twenty-three years of age. The non-symmetrical position of the lenses in this case was of interest, and the question arose as to what influence glasses which the patient had worn might have had in producing divergence in the left eye, which is now going on, the right eye doing the work. The immunity for three years and freedom from trouble favored strongly the opinion that the glasses had not entered as a factor in the etiology of the divergence.

A sketch of a case by Dr. J. M. Taylor, which occurred in the practice of Dr. C. S. Turnbull, of Philadelphia, was also presented. The patient wore glasses with comfort for more than a year, when he was accidentally killed.

The paper was discussed by Dr. Mittendorf, of New York, who related the history of a case.

Dr. GEORGE T. STEVENS, of New York, then read a paper on

THE EMPLOYMENT OF NITROUS OXIDE AS AN ANÆSTHETIC IN OPHTHALMIC OPERATIONS.

He had employed it in operations about the nasal duct, iridectomy, cystotomy, and similar short operations, and believed that it possessed several advantages, such as being less dangerous, unattended with nausea and other symptoms which are incident to the use of ether, and that it demanded for its administration far

less trouble than ether or chloroform. He thought it doubtful if it could be relied upon for cataract operations.

THE PRESIDENT had employed it more or less during the last ten years, and stated that the oxide had the advantages claimed for it to a certain extent. He had, however, noticed two features: first, there is apt to be a good deal of rigidity on the part of the patient in some cases; second, it is apt to be attended with a great deal of venous congestion which gives rise to considerable hemorrhage in wounds about the eye.

Dr. R. H. DERBY, of New York, had employed the nitrous oxide preliminary to prolonged anæsthesia with ether, and with very gratifying results.

Dr. BULLER, of Montreal, said that for some time nitrous oxide was used in the Moorfields Hospital in London, but with unsatisfactory results. He had resorted to the primary anæsthesia produced by ether with exceedingly gratifying results.

Dr. ALBERT G. HEYL, of Philadelphia, then presented

A CONTRIBUTION TO THE OPERATIVE TREATMENT OF GLAUCOMA.

After giving the ordinary method of treatment employed, and detailing the history of a case which had been under his observation, and in which he had resorted to operative treatment, he recommended the following plan as a modification of that which he had employed. It was to ligate the frontal artery and then open the supra orbital artery and allow a few ounces of blood to escape, and then close the vessel with a ligature. He discussed at considerable length the physiological basis of the operation, and said that he wished simply to place upon record a piece of clinical experience which he thought would shed some light upon the condition of acute glaucoma. The patient upon whom he operated was suffering from chronic glaucoma when he saw him, but the case had been one of acute glaucoma in its inception.

Dr. WEBSTER, of New York, recalled a case in which a California surgeon advocated the ligation of the carotid early for glaucoma, performed the operation once and cured his patient.

THE PRESIDENT stated that the natural history of acute glaucoma must be considered before deciding with reference to the influence produced by any modification of the circulation by operation.

Dr. SEELY, of Cincinnati, said it should be borne in mind that the influence of the Californian operation was directly the reverse of that suggested by Dr. Heyl.

Dr. GUSTAVUS HAY, of Boston, then made a communication on the

ASTIGMATIC PENCIL.

It was discussed by Dr. Knapp, of New York.

Dr. CHARLES J. KIPP, of Newark, N. J., then reported cases of

SARCOMA OF THE CHOROID WITH INTERESTING CLINICAL FEATURES.

The first case was that of a woman seventy years of age, first seen six weeks before the eye was removed. Sight had been lost only a few months. There was no pain, nor was there any sign of inflammation of outer parts of the eye. In the outer half of the eye behind the lens was seen a large white mass of round form, on the surface of which were numerous hemorrhages. The retina was detached in the inner half. The diagnosis of intra ocular tumor was made and enucleation advised. Four weeks later symptoms of secondary glaucoma developed, and after the patient had endured the pain for two weeks she consented to have the eye removed. The operation was not attended by accident, and the wound healed rapidly. On examination of the eye a large dark tumor was found which nearly filled the eye, and which had started from the outer half of the choroid. It was

covered in part by the retina, and extended anteriorly to and involved the ciliary body. It consisted of spindle-shaped cells, and contained much pigment.

The second case was that of a man thirty-four years of age, who was first seen seventeen months before enucleation was performed. At that time the anterior parts of the right eye were apparently quite healthy. On the nasal side of the eye a semi-globular protuberance was seen to project nearly to the visual axis; upward and downward it extended apparently nearly to the vertical meridian. Anteriorly it did not reach quite to the ciliary processes. The tumor was of a greenish-red color, and was covered by transparent retina; its surface was smooth, and its vessels were distinctly visible. The retina was slightly detached at the base of the tumor, but nowhere else. The optic disk was very pale and its margin slightly blurred. The other parts of the choroid and retina presented nothing abnormal except an atrophic patch in chord below disk. Tension was normal; visual field defective in outer half, and much contracted upward, downward, and inward. The other eye showed numerous atrophic spots in choroid and pigment deposits in retina. From the patient it was learned that twenty years ago he had had a severe attack of some eye disease which seriously impaired the left and somewhat the right eye, the one now containing the tumor. Since then his sight remained the same until two months ago, when he noticed that his right eye failed. The disease from which he suffered twenty years ago was doubtless a choro-retinitis, the results of which were plainly visible in both eyes. Seventeen months later the patient was seen again. There was now great pain, and the eye presented the usual symptoms of secondary glaucoma. The eye was enucleated and the wound healed rapidly. On examination the tumor was found to have started from the choroid in the region of the macula lutea. It was very large. The retina was detached completely. The microscopical examination of the tumor showed it to be a spindle-celled melano-sarcoma.

The third case was that of a woman forty-one years of age, who was first seen fifteen months before the eye was enucleated. At the first examination nothing abnormal except a prominence and opacity of the retina at macular region was found. The retina for a space of about two diameters of the optic disk was grayish, and the retina veins here were dark in color. The summit of the prominence was best seen with a +4 dioptric glass. The retina was not detached, neither over the prominence nor anywhere else. The eye was as it had been practically blind for some months. The case was seen from time to time for two months, during which period no marked change in the eye was observed. Thirteen months later she was seen again. She had the secondary glaucoma, which had come on about two weeks before. The eye was enucleated and the wound healed rapidly. On examination a large tumor of irregular form, and with very broad base was found, which originated in the region of the macula lutea and from there spread over the optic.

The fourth case was that of a woman forty-two years of age. Sarcoma of the ciliary body and iris. Secondary glaucoma was present when the patient was first seen. The tumor did not extend to the choroid, and the microscopic examination showed that it had probably originated in the connective tissue of the ciliary muscle. It was composed of spindle-cells and contained much pigment. Five years after the operation there was no relapse.

Dr. Kipp also read a paper describing a case of very extensive ossification of the choroid occurring in a young man who, when first seen ten years ago, had a chalky cataract, to which the pupil was everywhere adherent. As there were at that time no symptoms of irritation of the eye, and the case was hopeless so far as sight was concerned, no treatment was advised. The boy had been born with the cataract, according to the mother's

statement. Ten years afterward the eye became painful and presented when then seen the appearance of iridocyclitis. The eye was removed, and on examination the osseous plate lined the inner side of the choroid and as far as the ciliary processes.

The communication was discussed by Dr. Howe, of Buffalo, who presented a specimen, the President, and Drs. Mittendorf and Webster, of New York.

DR. S. THEOBALD, of Baltimore, then read a paper on

TRITURATION OF THE CORTEX.

He reported two cases in which this operation was practised in connection with preliminary iridectomy to hasten the development of slowly ripening cataracts. The operation consists in a kneading or bruising of the anterior cortical layers of the lens by pressure on the cornea after iridectomy and while the anterior chamber is still empty, and is in accordance with the suggestion put forth by Professor Förster, of Breslau. The trituration was done with the angle of the strabismus hooks, and in the first was imperfectly performed. In the second case the operation was performed with the smooth end of the Bowman tortoise-shell cataract spoon, which seemed better adapted to the purpose. In the first the operation was followed by but slight change in the condition of the lens. In the second case, however, a very rapid development of the cataract ensued. In each case there occurred a sufficient amount of iritis to cause slight but persistent adhesions between the iris and lens at the pupillary angle of the coloboma, and in the second case it was found by oblique examination a day or two after the operation that near the cut edges of the iris the pigment layer had been detached from the muscular coat in a manner which was quite peculiar. That the iris should be more or less bruised as well as the lens, however carefully trituration be performed, appears unavoidable, and the risk of exciting inflammation in this manner seems the chief objection to the procedure. It would appear, however, that Professor Förster has not had serious trouble from this source, as he makes no special reference to it in his paper.

DR. GRUENING, of New York, had performed the operation twice during the last year. In the first he performed large iridectomy upward and with the angle of the strabismus hook trituated the lens in the *area of the pupil only*. No iritis followed, and the lens became completely opaque within one week. He extracted it three weeks later with very good results. In the second case he performed iridectomy upward and again treated the lens only in the area of the pupil, and in four days the lens was completely opaque. He thought there were certainly cases in which the operation was indicated, and was attended with great gain.

DR. KIPP said that he performed the operation some time ago, the lens became opaque, and four or five days afterward it cleared up again.

DR. MITTENDORF, of New York, thought the operation was indicated, especially in certain cases in which two cataracts were forming, and his experience in the operation had been equally favorable with that reported by Dr. Gruening.

DR. KNAPP, of New York, had performed the operation once; but it did not seem to hasten the ripening of the cataract.

DR. WADSWORTH, of Boston, had performed the operation once in a patient eight years ago. There seemed to be no effect at all, so far as ripening of the cataract was concerned. He thought that probably in some cases maturity of the cataract might be hastened very much by the method, while in other cases probably the result would be very slight.

THE PRESIDENT had operated eight times, and in seven cases had subsequently performed extraction. In one case marked iritis developed, but did not interfere with the subsequent recovery, and extraction was entirely satisfactory. He hoped to make a communication upon the

subject which would embrace the history of all his cases, with remarks.

DR. GRUENING remarked that by the area of the pupil he meant the new pupil, including the coloboma.

The paper was further discussed by Drs. Webster, of New York; Fox, of Philadelphia; Dyer, of Newport, and Theobald, of Baltimore.

The Society then adjourned to meet at 9 A.M. July 19th.

SECOND DAY—THURSDAY, JULY 19TH.

The Society was called to order at 9 A.M. by the President.

THE TREASURER moved that the annual assessment be five dollars. Adopted.

VASELINE CERATE A CONVENIENT BASIS FOR OINTMENTS INTENDED FOR APPLICATIONS TO THE EYELIDS.

DR. THEOBALD, of Baltimore, read a brief paper on the above subject, in which he stated that he had been using with much satisfaction for several months, both in private and in hospital practice, as a basis for ointments intended for application to the eyelids, a cerate made of yellow wax and vaseline, which is prepared without difficulty by melting the wax and vaseline together by gentle heat, and stirring the mixture until it hardens, combining one part of yellow wax with four of vaseline, which proportion gives the ointment sufficient firmness, except, perhaps, in very hot weather, when the proportion of wax may be increased to one to three. Dr. Theobald also exhibited a specimen of ointment of the yellow oxide of mercury, containing two grains to one drachm of vaseline cerate, which, though prepared nearly four months since, and kept with no special care, still retained its bright yellow color and had undergone no appreciable change. He had been told that cerates prepared by vaseline were in use, but was not aware that attention had been called to the convenience of employing them in the manner suggested.

DR. H. KNAPP, of New York, then read a paper in which he reported a case of

BLINDNESS FROM RETINAL THROMBUS IN CONSEQUENCE OF FACIAL ERYSIPELAS.

There is on record a certain number of cases of blindness in consequence of facial erysipelas. Their symptoms vary considerably. There is lack of ophthalmoscopic examinations during the first stage of the affection. Not long ago Dr. Knapp had the rare opportunity of observing such a case almost from the beginning to the end. Mr. E. F.—, forty years of age, had lived in the tropics, had had syphilis with secondary and tertiary symptoms which were aggravated when his business called him north. On March 20, 1883, while in New York, he had an attack of erysipelas which began upon the nose, proceeded to the pharynx, cheeks, and orbits. The patient was under the care of Drs. Gulecke and Schottke, who kindly allowed Dr. Knapp to publish the case. The erysipelas progressed, and on March 28th he was totally blind in both eyes. Reserving a detailed discussion of this case for publication in the "Archives of Ophthalmology," Dr. Knapp restricted himself to the following remarks:

First.—The blindness was produced by compression of the central retinal arteries and subsequent thrombosis of the retinal veins, both having been directly observed with the ophthalmoscope one day after the occurrence of the rapid, almost sudden loss of sight.

Second.—The ophthalmoscopic appearances observed from beginning to end showed no neuro-retinitis, but the successive stages of a thrombosis.

Third.—The degrees of the swelling of the orbital tissue or the establishment of collateral circulation from the choroid permitted the return of a limited flow of blood into the retinal arteries, which, however, was impeded by the blocked veins, leading to renewed extrava-

sation to the thrombosis and shrinkage of the arteries, and finally to atrophy of the optic nerve.

Fourth.—Perivasculitis played no, or only an unimportant part in the pathology of this case.

Fifth.—The white segments in the veins and arteries were white thrombi and not hypertrophy of the walls of the blood-vessels.

Sixth.—The thrombus was present in all probability also in the orbital veins, but did not, as in other cases, extend to the cerebral sinuses.

The paper was discussed by DR. KIPP, of Newark, who stated that the cases in which he had seen the condition described by Dr. Knapp, the retina and its immediate vicinity was in a state of inflammation or, at least, opaque, but not between the veins; by DR. KNAPP, who thought that the segments of the veins becoming white could be used as a diagnostic symptom of embolism; by THE PRESIDENT, who had seen a case in which the process was confined more particularly to the optic nerve, with swelling and neuro retinitis, and subsequent atrophy and nearly absolute blindness; and by DR. SEELY, of Cincinnati, who had seen a case in which iodoform used as a dressing had produced facial erysipelas in three distinct instances.

DR. KNAPP felt certain that the iodoform had no unfavorable influence whatever in his cases.

DR. W. H. CARMALT, of New Haven, Conn., read a paper on

CHANGES IN REFRACTION RESULTING FROM A BLOW.

R. A. S.—, twenty years of age, student in the sophomore class in Yale College, myopic since twelve years of age, consulted him on October 23, 1882, stating that while practising in the gymnasium the day before, he had fallen violently forward, striking his right eye upon a bolt projecting from the floor. The blow was sufficiently severe to give rise to disturbance that obliged him to keep quiet for the remainder of the day and evening, neither going about nor studying. But at the time of his visit he felt quite well again, except with reference to his eye, wearing his glasses habitually for all purposes of vision, near or far. He now felt an uncomfortable sensation in looking through his right glass, and could see much better at a distance without it, better, indeed, than he remembered ever to have seen before without glasses, but for all that he had a very confused sensation when looking with both eyes either with or without glasses. Four months afterward he was again consulted, when he found on ophthalmoscopic examination that there was no conus at the nerve, nor other evidence of retino-choroidal trouble. By oblique illumination no opacity of the lens was detected. On the following day he saw, at Dr. Carmalt's suggestion, Dr. Loring, of New York, in consultation. To summarize the facts of this, to his knowledge, unique case, it seemed established that in a case of myopia of very considerable and nearly equal degrees in the two eyes, one was reduced by the impact of a blow to a condition of astigmatic myopia which resolved itself finally into a cross astigmatism without any loss of acuity of vision or range of accommodation. After endeavoring to account for the mechanism of this change, five possibilities presented themselves: 1, a change in the shape of the cornea; 2, a diminution or shortening of the axis of the globe; 3, a displacement or dislocation of the lens backward; 4, a change in the relative position or arrangement of the lenticular fibres; 5, a pre-existing spasm of accommodation, the tonic effect of which had been released by the paralytic effect of the blow.

Dr. Carmalt excluded, as did also Dr. Loring, change in the length of the eyeball, also dislocation of the lens, also the previous existence of spasm of accommodation. The remaining alternative cannot be urged from any knowledge we have of such a condition having been positively determined. It is urged rather as a refuge, all the other explanations having been disproved or not being

satisfactory. Is it not possible that a sudden and violent impulse could have shaken and so displaced the denticulate articulations of the lens fibres that they became fastened in a position to correspond to (or cause) the error of refraction indicated above?

The paper was discussed by Drs. Knapp, Noyes, Seely, Webster, Buller, McKay, and F. B. Loring.

DR. E. W. BARTLETT, of Milwaukee, Wis., then read a paper entitled

A FURTHER MODIFICATION IN CATARACT EXTRACTION.

The modification proposed is to make the preliminary iridectomies in certain difficult cases, one upward and one downward. Dr. Bartlett then reported two cases which illustrated the modification. The modification was suggested in difficult cases only, as when the eye is very prominent, when the iris does not react to atropine or attachments have formed between the iris and capsule, when the one eye has been lost and the least amount of risk should be taken with the other eye, and when the patient is very infirm and danger from shock is very great, and when the cataract is maturing very slowly. In such cases this modification gives the patient a better chance of securing a certain amount of sight than the method of making the whole operation at one time.

DR. GRUENING, of New York, then read a paper entitled

BLEPHAROPLASTY ACCORDING TO THE ENGLISH METHOD.

A young man sustained an injury of the face by the explosion of a petroleum lamp. As a result of the mishap the integument of almost the whole forehead, the right temple, the right cheek and corresponding half of the nose was changed into dense cicatricial tissue. The upper lid was wholly everted and its free border attached to the supra-orbital margin. To correct the deformity the lid was detached from the orbit, the neighboring tissues undermined, the deep scar excised, the free border of both lids brought in apposition and united by free sutures. The surface of the wound measured 40 mm. in the vertical, and 55 mm. in the horizontal direction. In order to cover the defect a flap was transplanted from the inner surface of the left arm and placed upon the wound. The flap was prepared according to Wolfe's suggestion, *i.e.*, deprived of its subcutaneous cellular and adipose tissue. After careful coaptation of the flap to the edges and the surface of the wound gold-beater's skin and a bandage were used to maintain the flap in its position. No discoloration, no displacement of the flap ensued; it united firmly with the wound, and the ectropion was corrected. To-day, *i.e.*, nine months after the operation, the flap measures 15 mm. in the vertical, and 30 mm. in the horizontal direction. The shrinkage took place during the first four weeks after the operation. No further shrinkage during the last eight months. The result is very satisfactory, and would not have been obtained by any other method.

The paper was discussed by Drs. Wadsworth, of Boston; Kipp, of Newark, and Andrews, of Staten Island.

DR. MCKAY, of Wilmington, then reported a case of

LOSS OF AN EYE FROM SEWER-GAS AFTER EXTRACTION OF A CATARACT.

John H—, a German brewer, sixty-one years of age, was operated upon April 16, 1882, for senile cataract, without an anæsthetic, by Graefe's method of linear extraction. The upward operation was performed satisfactorily, and without any accident whatever. He counted fingers immediately after the operation. The eye was covered with absorbent cotton and a light flannel pressure bandage without the further introduction of a mydriatic. Three and a half days after the operation the bandage became somewhat loosened. This eye was examined, and atropia was introduced. The incision had closed, the cornea was clear, the pupillary field dark, and vision, tried for a moment, was very encouraging. The

patient subsequently developed symptoms of some general disease, evidence of contamination of the atmosphere by sewer-gas was detected, and finally the eye was lost, as Dr. McKay believed, in consequence of the poisoning of the general system produced by this noxious agent.

DR. MCKAY also reported a case of

SYMPATHETIC NEURO-RETINITIS OCCURRING DURING PREGNANCY.

The patient was twenty-six years of age; she had been married ten months. In infancy she had scarlet fever, since which time the right eye had been weak. Five years ago the eye was treated for a painful inflammation by an oculist in Philadelphia, but during the last two years it had not annoyed her. When Dr. McKay saw the patient the eye was in a quiescent state of chronic irido-choroiditis with partially occluded pupil and dense opacity of the vitreous. She complained of her left eye, and reported that after a week's crocheting a sudden pain was felt in it while looking at a white wall. She was debilitated by malarial and pulmonary troubles and was three months advanced in pregnancy. Ophthalmoscopic examination revealed hypermetropia and a faint opacity of the deep portion of the vitreous, with decided congestion of the optic disk and retina, and within two weeks the appearances of sympathetic neuro-retinitis were fully manifested, and vision was reduced to counting fingers six to eight inches in a dimly lighted room. After three months' treatment in a darkened room, with a dark bandage over her eyes, and the occasional use of a solution of atropia to prevent iritic adhesions, inunctions of mercurial ointment to the temples, several leechings to the left temple, and a general sustaining and tonic treatment, she improved in general health, and the vitreous opacity as well as the exudation of the optic nerve and retina disappeared, and she recovered good vision. Her pregnancy, Dr. McKay thought, greatly modified the course of the sympathetic neuritis favorably. The ophthalmoscopic appearances of retinitis albuminuria were looked for repeatedly, but never were found, and the fact of her vision not being again impaired while she had general anasarca, which developed later in the progress of the case, enabled him to regard it as a case of neuro-retinitis.

DR. L. HOWE, of Buffalo, then read a brief paper and presented a specimen which illustrated

THE DIFFICULTIES IN MAKING A DIFFERENTIAL DIAGNOSIS IN GLAUCOMA.

The patient was four months old. When first seen, two months of age, a yellowish reflex was noticed in the interior of the eye which had been previously somewhat reddened, and vision, so far as could be determined, was much impaired. Increase of tension was scarcely perceptible, but after some hesitation it was regarded as + 1. After enucleation it was found that the entire vitreous had contracted into a small cone as a result of previous inflammation, and that the apex touched the retina, having its interior filled with a semi-purulent yellowish substance.

DR. E. E. HOLT, of Portland, Me., then read a paper entitled

COMMOTIO RETINÆ, OR SOME OF THE EFFECTS OF DIRECT AND INDIRECT BLOWS TO THE EYE.

Dr. Holt reported four cases. In two of these the patient was struck more or less directly by a stick of wood, in one by a round rod or cane, and in the other by a flat piece of coal, striking the forehead, nose, and cheek, not hitting the eye itself. In three cases recovery was uninterrupted. In one there was a relapse. Vision was reduced to a perception of light for four days, after which it began to return, and in the course of two weeks became nearly normal. Relapse then occurred and vision sank, but not so low as it was after the receipt of the injury, and recovery with a perfect eye took place

much more slowly than at first. Dr. Holt gave a detailed history of this case and also of one of the others.

THE PRESIDENT remarked that Dr. Holt had reported four cases manifestly dissimilar in character. From a thorough study of the affection referred to he had become convinced that commotio retinae is a phenomenon which had been entirely explained upon the supposition of a fissure running through the optic foramen of the orbit, and is almost entirely mythical when taken by itself.

DR. SEELY, of Cincinnati, thought the subject could not be dismissed so summarily as Dr. Noyes had supposed. He had reported one case which could not be explained away so readily, because a single application of electricity restored a vast amount of vision, and there was no explanation of the extreme lowering of the vision from which the patient suffered.

DR. KIPP referred to a case in which there was a fracture and subsequent blindness, and suit was brought for damages. The question which arose was whether the case was one of congenital blindness with divergence, or was it due to injury. On further examination of the patient and the surroundings he discovered that the mother had the same condition in the corresponding eye, and taking this into consideration he concluded that the blindness was not due to the injury.

The paper was further discussed by Drs. Gruening, Knapp, Wadsworth, and McKay.

A paper entitled "Two Cases of Ophthalmoplegia Externa, Associated with Disease of the Optic Nerves from Brain Tumor, with an Account of the Post-mortem Examination," by DR. CHARLES STEADMAN BULL, of New York, was read by title and referred to the Committee on Publication.

INJURY TO THE EYES BY HANGING.

DR. F. B. LORING, of Washington, said that since the series of experiments reported by Dr. Dyer, he had seen no communications concerning the effect produced upon the eyes by hanging, except the case reported by Dr. Green, of St. Louis, which was not corroborative. He had had opportunity to observe one case, which he wished to place upon record. In that instance both eyes were affected, although one was not affected so markedly as the other.

DR. GREEN remarked that his case was not corroborative of Dr. Dyer's conclusions in a certain sense, but he did not consider it valuable either as corroborative or otherwise, because the time limited for examination after the execution was too short, not being more than one hour.

DR. HOWE, of Buffalo, referred to one case in which he examined the eyes thirty-five minutes after the execution, and was unable to see any change.

DR. R. H. DERBY, of New York, referred to three cases which he had already reported in which there were marked changes in the eye produced by hanging.

COLOBOMA OF THE CHOROID.

DR. MCKAY, of Wilmington, wished to place on record three cases. In one there was coloboma of the iris. Two cases occurred in children, aged respectively seven and ten months. The other occurred in a woman twenty-eight years of age. In the child seven months of age the coloboma of the iris occurred.

DR. THEOBALD, of Baltimore, presented an additional modification of his bandage, which he regarded as a substantial improvement. It consisted in cutting the eye-piece biasing in order to prevent the tendency to wrinkling.

DR. MITTENDORF called attention to a new method of applying remedies to the eye, namely, in the form of impalpable powders or triturations. He presented several specimens of remedies prepared in this way.

THE PRESIDENT remarked that he had employed homatropin prepared in this way, and had been well pleased with the preparation.

DR. JONES asked if this method was preferable to the disks prepared by Savory & Moore.

DR. WADSWORTH, of Boston, spoke of the loss of power in a solution of eserine. Recently he had found a solution which was three years old, and it still worked perfectly well.

DR. SEELY, of Cincinnati, said that for ordinary purposes he preferred an old solution of eserine to a fresh one.

The following officers were elected for the ensuing year: *President*—Dr. H. D. Noyes, of New York; *Vice-President*—Dr. William F. Morris, of Philadelphia; *Secretary and Treasurer*—Dr. R. H. Derby, of New York; *Publication Committee*—Drs. E. G. Loring and D. B. St. John Roosa, of New York.

The place of holding the next annual meeting is Kaaterskill, N. Y., and the time the third Wednesday in July.

The Society then adjourned.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 14, 1883, to July 21, 1883.

MAGRUDER, D. L., Lieutenant-Colonel and Surgeon. Medical Director Headquarters Department of the Missouri. Granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 145, Department of the Missouri, July 12, 1883.

ELBREY, FREDERICK W., Captain and Assistant Surgeon. The leave of absence granted on Surgeon's certificate of disability, by S. O. 26, A. G. O., January 31, 1883, further extended six months on Surgeon's certificate of disability. S. O. 162, A. G. O., July 16, 1883.

POWELL, JUNIUS L., Captain and Assistant Surgeon. Assigned to duty at Fort Columbus, N. Y. H. S. O. 130, Department of the East, July 18, 1883.

RICHARD, CHARLES, First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Adams, Newport, R. I. S. O. 130, Department of the East, July 18, 1883.

PERLEY, HARRY O., Captain and Assistant Surgeon. Assigned to duty at Fort Pembina, D. T. S. O. 118, par. 1, Department of Dakota, July 5, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending July 21, 1883.

SCOTT, HORACE BROWN, appointed as Assistant Surgeon.

RUSH, CHARLES W., Assistant Surgeon, promoted to Past Assistant Surgeon.

DIEHL, OLIVER, Assistant Surgeon, promoted to Past Assistant Surgeon.

BRYAN, J. H., Assistant Surgeon, promoted to Past Assistant Surgeon.

GATEWOOD, J. D., Assistant Surgeon, promoted to Past Assistant Surgeon.

WHITE, C. H., Surgeon, detached from the Lackawanna, and placed on waiting orders.

HEFFINGER, A. C., Past Assistant Surgeon, detached from the Lackawanna, and granted leave of absence for three months.

WOOLVERTON, T., Surgeon, detached from the Naval Hospital, Philadelphia, on July 31st, and granted leave of absence for one year, with permission to leave the United States.

MR. ALFRED ROBERTS, Surgeon to the Prince Alfred Hospital, New South Wales, has received the honor of knighthood.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending July 24, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
July 17, 1883....	0	18	38	4	68	23	0	0
July 24, 1883....	0	16	39	7	87	12	0	0
<i>Deaths.</i>								
July 17, 1883....	1	10	7	4	21	16	0	0
July 24, 1883....	0	4	11	5	19	10	0	0

HARDLY EVER—BROKEN.—Dr. F. H. Darby, of Morrow, O., writes: "I secure my thermometer case in the upper vest pocket, by wrapping it three or four times around near the shoulder with a common half-inch No. 00 rubber band. If the pocket is wide divide it in two compartments by a pin or a few stitches, the other side can then be very properly used for a pen-holder, comb, or pencil. For cheapness, the cost being a pin and a rubber band, simplicity, and facility of changing from one vest to another, we submit the above, if you will pardon egotism, as being *the very best of all*."

HOW PATENT MEDICINES PAY.—The *Milwaukee Sentinel* in a very sensible article on "Patent Medicines," truthfully says: "It is advertising that is the secret of success in the case of patent medicines, if there is any secret about it. There is not a patent medicine which is superior to the preparations provided for by the standard medical publications. It is much simpler, however, for the person who wants a medicine, to buy a bottle of patent medicine, good for every human ill, than go to a physician. By advertising a patent medicine extensively and persistently the people are brought to recognize certain common and simple sensations as evidences of a disease which this particular remedy will cure. About all that is required to succeed in the patent medicine line is money and nerve to use it in advertising. It makes no sort of difference what medicine it is—the combination of drugs is the item of least importance. It is well, perhaps, to put the drugs, if any are used, in spirits, so that a man can take his whiskey with a clear conscience—indeed, with a sense of his own worthiness in taking care of his health. Occasional changes in the name of the medicine and of the maker are desirable, for after a few years the public demands something new. The same medicine may be used, but a change of name and of the character of the illustrations is demanded. After a long run of a patent medicine as a cure for lung troubles, a new run may be established by calling it a remedy for stomach troubles. When a fortune has been made out of lung pads, they can be cut down in size and another fortune made out of them as kidney pads."

VIOLENT HEMORRHAGE FROM THE LEFT EXTERNAL AUDITORY MEATUS FOLLOWING A COLD ABSCESS—SUBSEQUENT RUPTURE OF THE LEFT INTERNAL CAROTID, CAUSING DEATH IN A FEW SECONDS.—Dr. R. B. Davy, of Cincinnati, reports the case of a little girl three years of age suffering from restlessness, coated tongue, sore throat, and slight fulness of left side of neck. In the act of examining the throat (the child resisting) an abscess of the left ear broke and discharged about a teaspoonful of reddish pus. After a few hours violent hemorrhage from the ear set in, and in the course of two days fully a quart of blood had been lost. Most of this quantity

was discharged at two bleedings, the pillows being stained only with small spots in the intervals. The hemorrhage ceased spontaneously and for nearly a week the ear discharged pus, gradually losing its reddish cast. The ear was examined with reflected artificial light and the membrana tympani found to be intact. The child was improving, though very pale. On the fifth day after the last hemorrhage another, quite as violent as the first, occurred. The ear was now plugged with a bit of sponge, which checked the bleeding. Simultaneous with the plugging there appeared a swelling about the size of the longitudinal half of a hen's egg extending from the left mastoid process downward and forward. This swelling increased in size until late in the afternoon, when the plug was forced out of the ear, the blood spurting at least a foot from the child's head and the swelling beneath the ear diminishing in size. The ear was now more firmly plugged and ice-bags applied to the swelling which had returned immediately. The next day the swelling was perceptibly smaller and had a leathery feel on firm pressure; but the third day afterward it again increased in size, and showed signs of suppuration, though there was no pointing externally. On the following afternoon the left internal carotid ruptured in the mouth, and the child bled to death in a few seconds. The post-mortem revealed at the site of the swelling a deep-seated abscess whose contents had come in contact with and injured the coats of the vessel in question, causing them to give way. The loss of blood during the fatal hemorrhage amounted to but little over half a pint. Careful inquiry was made but no history of hemorrhagic diathesis was obtained, and the doctor concluded that the first hemorrhage had been caused by ulceration of the coats of the posterior auricular artery. The case will be reported in full in the *Cincinnati Lancet and Clinic*.

THE RODS AND CONES in the ninth layer of the retina have generally been considered to have an important function in vision. Dr. Borysikiewicz has recently asserted that they are entirely absent in the eyes of tigers and leopards which he has examined. Yet these animals have acute vision.

CASE OF CUTANEOUS CALCULUS.—Dr. G. W. H. Kemper, of Muncie, Ind., sends us the following report: "On May 9, 1878, I removed by incision one of these rather rare morbid specimens. The patient, a lady, aged fifty-five years, stated that about twenty years previously a small tumor developed in the right eyebrow, and gradually grew to the size of a hazel-nut. She had experienced no pain from it until the last year before its removal, when its presence became rather annoying, and at times caused neuralgic pains by pressure upon the supra-orbital nerve. It probably began as a sebaceous cyst and eventually was transformed into a calcareous mass. I was uncertain of the character of the tumor until my knife came in contact with the stone. It is of an oval shape, rough surface, and weighs at this time seven grains. No further trouble was experienced after its removal."

TONSILS BY THE BUSHEL.—Dr. W. N. Williams, of Indianapolis, Ind., writes: "In the discussion on Dr. William C. Jarvis's paper, 'Tonsillotomy without Hemorrhage,' read before the American Medical Association at its late session in Cleveland, O., you report Dr. J. P. Thompson, of Indianapolis, Ind., as saying, 'He did not intend to overestimate in the least, but believes that, without exaggeration, he has excised *two bushels* of tonsils,' etc. (see page 667, MEDICAL RECORD, June 16, 1883). The italics are yours, Mr. Editor. Suppose we figure on that statement a little. A bushel contains 2,150 $\frac{1}{2}$ cubic inches (see 'Ray's Practical Arithmetic,' page 83. One thousandth Edition). Discarding the fractions, we have 4,300 cubic inches in the two bushels. Assume that each tonsil would occupy a space of one-half cubic inch, it would require 8,600 tonsils to fill out

his measure of two bushels. Now, if the doctor excised one tonsil each day in the year, it would have required twenty-three years, six months, and twenty-five days to have completed the job. If his instruments were in good order, and he really felt well, and excised a pair of tonsils each day, he could have done it in the little matter of eleven years, nine months, twelve days and a half. If Dr. Thompson has really excised two bushels of tonsils in his practice, how many bushels have our other specialists excised? Speak out, gentlemen, or acknowledge by your silence that the championship of America in tonsil-cutting belongs to Indiana. It may be if some other gentlemen were to file their broad axes, grind their hand-saws, spit on their hands and sail in, that they could capture the champion's belt at the next meeting of the American Medical Association."

CHLOROFORM NARCOSIS DURING SLEEP.—Dr. Hunter H. Powell, of Cleveland, O., sends us the following case bearing upon the subject of chloroform narcosis during sleep: "On June 15, 1883, I was called to see a boy four years of age, who had fallen upon a piece of glass and cut the palm of his right hand badly, I found him asleep and determined to try the experiment of chloroforming in that state, as I had been interested in the various articles bearing upon the subject which have lately appeared in *THE RECORD*. I took my time about it and found no difficulty in getting him fully under its influence, examined the wound for bits of glass, put in necessary stitches, and put on the required dressing before he became conscious. I believe this will become a popular method for administering chloroform to children and am surprised it has not been resorted to more frequently. By it we save the little ones from the fright with accompanying excitement experienced by many of them at the first approach of chloroform, a gain certainly to be desired for the sake of child, mother, and doctor."

THE METHODS OF MONTHLY NURSES.—Dr. Alexander, in a series of articles in the *Medical Times and Gazette* on the management of parturition and the puerperal state, remarks on the habit of nurses of having each some special point which she considers of importance in the management of labor cases, and which, in her ignorance of the true principle involved, she is apt to overdo, or to do wrongly. For instance, one dreading hemorrhage will compress every uterus; another will drench every woman with cold water, etc. He says the best plan of finding out these faults is to "blow up" the nurse generally when troubles arise that we cannot get at the origin of, and wherever she in her self-defence shows herself to be most zealous, it is *there* we must look for the errors that are producing the mischief.

AN ANALYSIS OF INDIAN TEA.—Water, 5.849 per cent.; extract, 37.800 per cent.; total ash, 5.790 per cent.; ash soluble in water, 3.667 per cent.; ash insoluble in water, 2.123 per cent.; ash insoluble in acid, 0.149 per cent.; insoluble leaf, 50.100 per cent.; tannic acid, 13.040 per cent.; theine, 3.240 per cent.

THE INSANE ASYLUMS OF ITALY.—Italy has sixty-two insane asylums, which contain 17,471 insane inmates; of these, 9,000 are men, 8,471 are women. Since 1877, the number of admissions has been constantly increasing.

ABSENCE OF VAGINA. UTERUS, OVARIES—ENORMOUS DISTENTION OF URETHRA, WITHOUT INCONTINENCE.—Dr. James F. Ferguson, Visiting Surgeon to the Charity Hospital, N. Y., relates the history of a prostitute admitted October 25, 1881. Father was consumptive; mother died of pulmonary hemorrhage. The patient was the tenth child. She denied all previous venereal trouble. Although eighteen, had never menstruated, nor did she give any history of vicarious phenomena. She noticed a pimple on the posterior commissure at the time of admission, followed by a discharge, with scalding on micturition. There were three small chancroids in the

posterior commissure. The chancroids were touched with carbolic acid and dressed with iodoform. On the 29th of November, the parts having healed, a further examination was made, when no vagina was found; the meatus urinarius and urethra were very much enlarged. The sores above mentioned prevented an earlier examination. The labia are well developed. An examination was made by Dr. Ferguson, with Dr. Walter R. Gillette and Dr. E. S. Peck. They failed to find a uterus or ovaries. Investigation was made by the finger in the urethra; also bimanual touch through the rectum, and by sounds. The outer portion of the urethra was greatly dilated; she did not have incontinence of urine. She was well developed—breasts well formed, also the nipples. The mons of normal size. The labia nymphæ and clitoris presented the usual appearance. In this very remarkable case the unusual feature is exhibited of a urethra largely distended, with no incontinence of urine.—*The Planet, New York*.

REPORT OF A CASE OF CYANOSIS IN WHICH THE INTERAURICULAR AND INTERVENTRICULAR SEPTA WERE BOTH DEFICIENT.—A correspondent has sent us an interesting report under the above title, but has omitted to affix his name. We shall be pleased to hear from him.

ECHINOCOCCI IN THE LIVER OF A CAMEL.—A large camel from the Central Park was brought to the hospital of the Columbia Veterinary College almost in a state of collapse. No previous history was obtained. The animal was only in the building for a few hours. At the necropsy the principal lesion worthy of note was found in the liver, which was filled with hydatid cysts, which resulted from the migration of the larvæ of the tænia echinococci. These cysts were in various states of retrograde change. Some were almost calcareous, some in a suppurative state, and some nearly cystic. The hooklets diagnostic of this lesion were easily demonstrated.—*Journ. of Comp. Medicine*.

A CASE OF TRANSMISSION OF TUBERCLE FROM THE HUMAN SPECIES TO THE DOMESTIC CAT.—In the culture of medical science in these days the question of the transmission of tubercle from animals to man is proposed. I take the liberty of narrating a fact referable to a diametrically opposite problem, namely, the transmission of tubercle from man to animals. The case was that of a cat, two years of age, which died tuberculous after having repeatedly eaten the expectorated matter from a lady who died soon after of phthisis. On my first visit, by request of the owner of the cat, the animal presented a cadaveric appearance, with a physiognomy of suffering, and stiff and lustreless hair. For some time previous it was noticed that it had lost its natural beauty and vigor, lost appetite and suffered from severe cough and other symptoms which threatened a fatal termination. The cat died and I made a post-mortem examination which verified my diagnosis. It was true tuberculosis. On opening the thoracic cavity I found white nodules of irregular form disseminated throughout the entire substance of both lungs, isolated or confluent and varying in size from millet seed to a grain of corn. I found some of these tubercles on the costal pleura, some on the pericardium, and, note the circumstance, only one (of the size of a grain of wheat) on the right side of the heart near the apex. I did not have time to examine these nodules microscopically. Examined thus superficially I found variation in their consistency, some hard and calcareous, others soft and containing pus. Will these data be sufficient to prove the cat tuberculous? I believe so. (*G. Brezzo in Il medico Veterinario*).—*Journ. of Comp. Medicine*.

DENVER, COLORADO.—There are more physicians in Denver in proportion to the population than in any other city in the United States, says the *Denver Medical Times*. A Microscopical Society has recently been organized and a Woman's Hospital established.

ON SOME RECENT ADVANCES IN THE SURGERY OF THE URINARY ORGANS.

BEING THE ADDRESS ON SURGERY DELIVERED BEFORE THE FIFTY-FIRST ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION, AT LIVERPOOL, ON AUGUST 1, 1883.

BY REGINALD HARRISON, F.R.C.S.,

SURGEON TO THE LIVERPOOL ROYAL INFIRMARY.

(Special for THE MEDICAL RECORD.)

Mr. President and Gentlemen:

THE honor of addressing you on this occasion having been conferred upon me by your Council, I cannot enter upon the task that is before me without expressing my consciousness of inability to accomplish it in the manner I would desire. This sense of insufficiency is by no means lessened when I look at the names of those who have preceded me; when I remember the interest with which I, in common with you, listened to their words; and when I consider how completely abreast this great Association is kept by means of its *Journal* with everything relating to the advancement of surgery. On the other hand, long connection with this Association gives me the assurance of having to address a sympathizing audience, one disposed to overlook defects in any honest endeavor to set forth the advancements made in our art.

Surgery, I need hardly tell you, has long been cultivated in the new city which has now the honor of receiving you. The hospitals of Liverpool and their records show that the same ardor prevails here as elsewhere, both at home and abroad, while its position as a school of surgery indicates that it has entered not unsuccessfully into honorable rivalry with its competitors. But it may be asked, especially by those visiting Liverpool for the first time, Are there no traditions here? Are there no footprints of those who have left behind them works which place us in their debt, and which will render their names famous wherever and as long as surgery is known? It seems to me that one advantage connected with the itinerant character of our meetings is, that places suggest references to local celebrities of the past whose works cannot be thought over without advantage. In our desire to push forward, we sometimes forget to look back, and to reflect upon that which has been achieved and how it was brought about. Such reflections cannot fail to be of service in reminding us that surgery is not entirely of modern creation, that we have a few distant relations whose connection it is desirable to keep up, and that there still remain links which associate us with the great ones of the past. These links connect us, not here alone, but everywhere, with the names of Park and Alanson, to whose work I now wish for a moment to refer.

Henry Park was surgeon to the Royal Infirmary from 1767 to 1798. I cannot do better than quote a passage which our local historian, Sir James Picton, has selected¹ as paying a deserved tribute to his memory: "In the latter portion of the last century, when a vigorous flash of originality seemed to light up the annals of surgery, Park, of the Liverpool Infirmary, may be said to have

accomplished the first act of conservative surgery. His patient being a sailor, to whom the loss of a foot and leg would have been tantamount to the loss of his means of getting bread, determined him to make the experiment of simply excising the diseased part, the knee-joint, and retaining the foot and leg. This he did so successfully that, to use his own words, the patient some years after the operation 'made several voyages to sea, in which he was able to go aloft with considerable agility, and to perform all the duties of a seaman; that he was twice shipwrecked, and suffered great hardship without feeling any further complaint in that limb.' This was a crucial test of success, that should have stamped the operation as one of the greatest surgical triumphs of the time; but, like so many other great strides taken in that age of extreme vivication, it was in advance of its fellows, and was destined to be arrested for the better part of another half century."

I need not on this occasion dwell on the claims that excision of the knee-joint has to be regarded as one of the recognized operations in surgery. Though there may be differences of opinion in reference to the circumstances indicating it, there can be no doubt that it will for ever remain as a brilliant memorial of the surgeon whose name is associated with it.

Of Mr. Alanson, Park's colleague, and surgeon to the Royal Infirmary from 1770 to 1794—whose work has been aptly referred to by Mr. Sampson Gamgee¹ as "one of those forgotten surgical classics which I would venture strongly to impress on the attention of my younger brethren"—I will speak in the following passage from the Presidential Address of the late Dr. Vose, delivered on the last occasion this Association met in Liverpool: "To Mr. Alanson, formerly a surgeon to our Royal Infirmary, we are indebted for many important suggestions, made at a time when the science of hygiene was but little regarded anywhere. His remarks upon the ventilation of hospitals, the use of iron bedsteads, the necessity of frequent whitewashing, and the establishment of sanatoria in the pure air of the country for convalescent patients, testify to the correctness of his professional judgment and to his zeal for the welfare of his fellow-creatures. It is by his treatise upon amputation, however, that the memory of this gentleman, as an original thinker in surgery, has the strongest claims to our gratitude and regard. He tells us that among upward of forty amputations performed upon the old system, which had come under his notice, ten died of tetanus, two of bleeding, three from mortification, four from exhausting suppuration; while eighteen experienced hemorrhage, and nearly all had excessive fever. Most of the patients suffered from exfoliation of bone—conical stumps or wounds that would not heal. After the adoption of his improved method of procedure he had the satisfaction of being able to announce that out of upward of thirty amputations, taken indiscriminately, which were performed at the Infirmary, not one died, and none had secondary hemorrhage, while in a month after operation the wound was either altogether or as nearly as possible healed in all the cases.

As is well known, in Alanson's method of amputating, provision was made for the covering in of the bone, after its section, by the integuments.

Such, then, are illustrations of the useful work which was being done by surgeons in this comparatively modern

¹ Edinburgh Review, October, 1872.

¹ Transactions International Medical Congress, 1881, vol. ii., p. 352.

city about one hundred years ago. Gratitude for improvements the value of which is still fully and freely acknowledged justifies the foregoing brief references to the work of these distinguished men.

The selection of material for presenting to you to-day has occasioned me no little anxiety. Following immediately upon an address which will for ever render our jubilee year memorable—an address in which justice was done by the distinguished representative of surgery from Ireland to the great subject of surgical progress generally, whilst its prominent features were forcibly brought out, I may well hesitate where to tread.

In considering the position of surgery as detailed in Dr. Stokes' admirable address, the thought naturally occurs that its diffusion is as remarkable as its progress. Compare, for example, the condition of surgery prior to the existence of our Association with its position as set forth in the columns of our own *Journal*, or in those of the other great representative of medical opinion in this country—the *Lancet*. In the former period departures from the ordinary routine of surgical procedure were confined to a few hands, and the benefits resulting from improved methods of treatment were shared in by a very limited number. Now, no sooner is a method of treatment or an operation proved to be efficient, than it is taken up and practised wherever scientific surgery can reach; the peer is no better off than the peasant, and the cottage hospital rivals in its successes its more palatial representative.

So beneficently catholic is our profession that it hails with the greatest satisfaction, not only the discovery of new means of relief, but the adaptation of others to a form which permits of their more general adoption and usefulness; while, on the other hand, it regards with suspicion all methods of treatment which unnecessarily restrict or conceal that which was intended for the common good.

I propose to occupy the remainder of the time at my disposal by a reference to some of the more recent advances and work in connection with the surgery of the urinary organs.

Commencing with the kidneys, we are at once struck with what surgery is doing for them. Until quite recently the diseases of these organs were regarded as belonging almost exclusively to the province of the physician, and probably they would have remained so had preventive medicine obtained fuller development.

A more extended acquaintance with the pathology of the kidney has brought to light conditions in which the work of the physician requires to be supplemented by that of the surgeon. Pain arising from an undue mobility of the organ, tumors, deposits, hemorrhages, and collections of fluid within it—all these morbid states are now recognized as capable of relief or cure by fixing, opening, or extirpating the abnormal or disordered organ; whilst numerous illustrations have already been afforded of the successful removal of stones from positions where they must have ultimately led to the disorganization of the kidney in which they had become impacted.

It would be premature at present to endeavor to formulate anything like precise rules in reference to the application of the various operations on the kidney to which I have briefly referred; they are at present comparatively new to us, and we must occupy ourselves in cautiously moving in the direction they indicate, and in collecting experience rather than in drawing conclusions other than very general ones.

Among many valuable contributions to the literature of this subject which have appeared, I would include one by Dr. R. P. Harris,¹ of Philadelphia, which contains an analysis of one hundred cases of nephrectomy. From this, as well as other communications which have more recently been published in this country, we may draw at least three conclusions of value, so far as the operation of extirpation of the kidney is concerned. These are—

First.—That nephrectomy has been the means of saving many lives under circumstances where no other method of treatment was likely to be of service.

Second.—That this operation has been practised in cases where the probability of a successful termination appeared to be very remote.

Third.—That a method of effecting the removal of the organ different from that which was selected, or a procedure less heroic, might, in some instances, have tended to increase the chances of success.

In these directions then—in selecting cases for operation, in rejecting others as unsuitable, and in determining relatively to the case in question the best method of procedure—I take it that good work has yet to be done.

It appears to me that among the difficulties we have to contend with in the application of nephrectomy, two stand out prominently: 1, the kidney it is proposed to remove may be the only one; 2, the opposite organ may be similarly affected, though in a less degree, yet sufficient to interfere with those compensatory changes being carried out which are essential when one excretory organ has to supply a lack of service on the part of another. The literature of this subject will already be found to illustrate the class of difficulties to which I am referring.

The lesser proceedings, which include the exploration of the kidney, and the removal of calculi and of pent-up fluid, are necessarily attended with a diminished risk, and have already proved of much value.

In undertaking a new class of operations, we must bear in mind the past history of many methods of treatment, now justly regarded as successes, but which severally had a very unpromising commencement. Look at the unsatisfactory position held by ovariectomy only within a period represented by the memory of the majority of us here present to-day. Yet the high dignity to which it has been raised in the rank of surgical operations, by the skill and enterprise of Sir Spencer Wells, Keith, and others is frankly and fully admitted by the whole medical world.

In the treatment of certain affections of the bladder we shall find that much progress has been made, and that the way has recently been opened for prosecuting other important advances. These will be chiefly illustrated by the modern practice of lithotripsy and the treatment of tumors and intracystic growths.

Till a few years since the removal of stone from the bladder by crushing had been conducted on the lines laid down by Civiale some half-century ago. Though this method of proceeding has included amongst its advocates, past and present, surgeons of eminence, it cannot be said that as then practised it was either gaining ground or confidence. Indeed, I think I may say there was an increasing tendency to limit its application and to substitute lithotomy in all cases but those of the simplest kind. The mortality consequent upon the retention of broken calculi within the bladder was sufficient to induce all but the most ardent admirers of lithotripsy to hesitate to give it the preference over a proceeding in which, whatever might be the risks, there was at least a guarantee that the whole of the stone had been removed.

While the surgical mind was thus to some extent in doubt as to the limits to which the crushing operation of stone might safely be pushed, two important communications followed rapidly upon each other. That both of them should have emanated from America merely indicates that the desire to advance the art of surgery is not limited to the old country, but is a natural outcome of advancing civilization and humanity.

The first of these papers was by Dr. Otis, of New York, who demonstrated beyond all reasonable doubt, and in a manner which had not previously been attempted, that the male urethra was capable of safely receiving far larger instruments than were generally employed. Following upon this, and probably influencing the views of the author, came Dr. Bigelow's paper on the removal of stone from the bladder by crushing and withdrawing it at

¹ American Journal of the Medical Sciences, July, 1882.

a single operation; the latter communication clearly showing that the bladder was tolerant of much more prolonged manipulation than had previously been believed.

It appears to me that the originality of Bigelow in no way detracted from the importance of the work that had previously been done in this country and elsewhere, or compromised the acumen of those who were most interested in the progress of this department of surgery.

That Bigelow's method of procedure is a great step in advance—that it has extended the limits of lithotripsy and curtailed those of lithotomy—there cannot be the least doubt. But to suppose that it is capable of universal application, or ever likely to be so, is as unreasonable as to suppose that the art of surgery in no way differs from the art of administering Holloway's pills. But does the lithotripsy of to-day represent the finality of its perfection? I trow not. When we consider what chemistry, electricity, and other agencies are doing—how physical force is in many directions being supplanted by other means—can we doubt that there are yet improvements in store in the methods of effecting the destruction of concretions within the body? Nay, are there not already significant indications that such improvements are nigh at hand? Is it likely that the fruit of the labors of Garrod, of William Roberts, of Ord, of Vandyke Carter, and others has been already gathered? May not a more perfect knowledge of the physical and physiological laws which regulate the production of concretions in the human body result not only in enabling us more surely to prevent them, but to destroy them?

Considering the great activity that has within recent years been shown in demonstrating the preventable nature of many diseases and the energy that has been displayed in grappling with them, it seems remarkable that no adequate steps should have been taken to ameliorate the hygienic condition of certain parts of this country where the amount of calculus disease is excessive and the inhabitants consequently are exposed to an inordinate risk of contracting it. The admirable address by Mr. Cadge before our Association at Norwich, in 1874, furnishes abundant data for the further prosecution of inquiries of this kind.

I cannot help thinking that if it could be shown to be even probable that the dogs, cats, rabbits, or frogs of the aforesaid districts were inconvenienced in a like manner with their owners, the matter would long ago have been forced upon our legislature with all the exaggeration that usually characterizes agitations of this kind.

Though surgery has invariably shown itself equal to the circumstances and emergencies with which it has been called to cope—though the prevalence of stone in a district has always been compensated for, as far as this is possible, by the appearance of those most competent to deal with it—these are no reasons why such conditions should be permitted to continue. Had time or occasion offered, I think it would not be difficult to prove that circumstances, either fortuitous or by design, have been found to exercise a marked influence in diminishing or increasing, in certain places, the tendency to calculus disease.

One word in reference to lithotomy before I leave the subject of stone. There is no great operation in surgery, I believe, which furnishes more successful results than this. Taking the experience of the two hospitals in this city with which I have been associated, I find there have been within my recollection one hundred and two cases of lithotomy in persons of all ages, but chiefly in children, and operated on either by my colleagues or by myself. In only five of these cases could I ascertain that a fatal result followed. My late esteemed friend, and our former associate, Mr. Southam, speaking of his own experience of lithotomy at Manchester, informed me that he had operated one hundred and twenty times, and could only recall one death. In the great majority of the Liverpool cases the stones were not exceedingly large, and I have no doubt that many of them might

have been removed by lithotripsy. I question, however, whether the small mortality these figures indicate would thereby have been still further diminished, even if the calculation were made on a basis corresponding with the most successful statistics in lithotripsy that have hitherto been obtained.

Passing to tumors of the bladder, it is not surprising, seeing what has been done for tumors of the ovaries, uterus, and intestines, by Sir Spencer Wells, Keith, Lawson Tait, Treves, and others, that growths occupying the interior of the bladder should have received special attention. Though the literature relating to this subject has been of a somewhat fragmentary character, such compilations as Stein's recent work, "A Study of Tumors of the Bladder," conclusively show that some gratifying results have already been attained in both sexes. The great distress connected with this class of growth, the uncertainty as to the precise nature of the affection, in the first instance, and subsequently the kind of symptoms that accompany it, have naturally suggested the employment of means having for their object their removal by operation.

Sir Henry Thompson has done good service in giving prominence to the employment of digital exploration of the bladder, and in furnishing illustrations of the great advantage that this proceeding is capable of affording in suitable cases.

From a consideration of some of the extremely valuable records which have been published by various surgeons, where the bladder has been opened for the removal of tumors, it appears to me that it might have been better had the operative proceeding terminated with the detection and exploration of the growth by the finger. The chief dangers which experience has shown to be liable to attend the performance of this class of operations are:

1. The chance of rupturing a bladder, the coats of which have been rendered less resisting than natural.
2. The provocation of a hemorrhage which it has been found difficult to control.
3. An incomplete removal of the growth.

On the other hand, an examination of many tumors of this kind, of which villous growths or tufts furnish the best examples, shows that there is nothing in their connections or relations which need necessarily interfere with their complete removal. Precise information as to the presence and attachments of these growths we may now obtain with comparative safety. Whether their removal is to follow upon their discovery will be matter for further consideration.

With the view of extending our knowledge of these growths, a committee of this association is occupied in collecting information relating to them. The report of this committee, will, I hope, form the basis of an interesting discussion in the pathological section which will be opened by Mr. Paul.

I now come to speak of the prostate, and I shall do so in reference to the part it takes in obstructing micturition, for the reason that it is this symptom which in some form or other brings the patient under our care.

It appears to me that enlargement of the prostate is specially interesting to us in relation to its earliest and to its most advanced forms, and it is to these points that I shall more directly refer.

If we take the obstructive disorders of the urinary apparatus, and inquire what feature of them is most detrimental to the associated parts, the answer undoubtedly will be, the misdirection of the muscular force that is thereby entailed. How can we explain the structural alterations which take place behind the obstructed point, and which manifest themselves in different ways, except as the results of urinary retention and retrograding pressure? How frequently do we find, in cases of stricture or enlarged prostate, that the whole of the apparatus behind the primary constriction consists of little else than dilated saccules and tubes! Is not this back-pressure go-

ing on, though it may be imperceptible, from the moment that impediment arises to the escape of urine from the bladder? The more we study animal mechanics, either in their physiological or pathological application, the more can we appreciate the truism that force is never lost; if it is not permitted to act for good, it must be productive of evil; if it is not exerted toward the legitimate fulfilment of a normal act, it must inevitably exercise a corresponding pressure in an abnormal direction. Whenever I see in the post-mortem room an ordinary specimen of dilated kidney, tortuous ureter, or sacculated bladder, associated with an enlarged prostate or a stricture, the expression "misdirected force" almost involuntarily escapes from me.

Such considerations as these have long led me to believe that our treatment of prostatic stricture commences, as a rule, far too late; we delay until the bladder shows, by the formation of a pouch or a sacculi behind the prostate, the first bad influence of back-pressure before we seek to rectify it.

I have endeavored to prove how much good may be done by the adoption of judicious mechanical treatment on the appearance of indications that the prostate is commencing to obstruct micturition, and I have founded my suggestion upon a condition which may be seen illustrated in any museum—viz., one in which, though the gland has become large, obstruction has not been known to occur. An extended adoption of this practice has convinced me that the pressing symptoms connected with an enlarging prostate may be kept in abeyance by the timely employment of those principles of treatment which are generally recognized as being applicable to any tubes within the body which are threatened with occlusion, and are within our reach.

In the more advanced forms of prostatic enlargement, where the bladder has been converted into a receptacle little better than a chronic abscess in which urine stagnates, surgery has done much to afford relief.

When the comfort that catheterism is capable of affording has ceased to be effectual, other plans of establishing a drain for the urine are at our disposal. It is not necessary that I should discuss the various means of effecting this; let me, however, say a few words in reference to two which have more recently come under notice; these are—first, incision into the bladder from the perineum, and secondly, paracentesis through the enlarged gland.

For the purpose of securing a more or less permanent channel for the escape of urine from the bladder, other than that by the urethra, I must admit that following the practice of Syme, and to some extent of Edward Cock, I have a decided preference for an incision through the perineum, on the twofold ground of safety and comfort. We have had numerous examples of the great advantage that cystotomy is capable of affording for bladder affections, dependent on a large prostate—none perhaps more striking than the case narrated by Mr. Lund, on the memorable occasion of the meeting in London of the International Medical Congress. The paper closes with this observation: "I have thus placed on record this case, unique in its character, and interesting and encouraging in its results, with the hope that should a similar case occur to any surgeon now present, he will not hesitate to give his patient the chance of benefit from a course of procedure so simple in its nature, and so likely to be followed by temporary, if not permanent, benefit."

I may be permitted here to submit to your notice a method of puncturing the bladder through the enlarged prostate which has afforded very gratifying results. It consists in passing the trocar through the gland, and retaining it in the perineum, so as to afford a permanent as well as a convenient drain for the urine. I should have had more diffidence in commending this operation to your notice had it not received the approval of our distinguished associate, Professor Gross, whose contribu-

tions to the surgery of the urinary organs are held in deservedly high repute on both sides of the Atlantic.

Though the primary object of cystotomy, as usually practised, is merely to place the bladder at rest, by providing a continuous drain for the urine as well as the products of cystitis, it occurred to me, as it had already done to others, that it would be possible to extend this proceeding, with the view of removing those barriers to micturition which the hypertrophied gland so frequently presents.

It was to meet conditions such as these that Mercier introduced and practised division of the prostatic bar by means of a cutting instrument introduced along the urethra. This plan, though admirable in its conception, was open to the objection that in its execution it was necessarily uncertain, there being no means of ascertaining with certainty that the section was confined to the obstruction to be removed. On carefully considering the position of matters, as well as the proposals that had been made, it appeared to me more reasonable to attempt to divide the prostatic obstruction at the neck of the bladder from an opening made into the membranous urethra, than by means of instruments which had to traverse the whole length of the canal. I have recently brought under notice a case¹ in which I thought it desirable to explore the prostatic urethra from an opening made in the perineum, through which I was enabled to divide with precision a prostatic barrier. The division of this portion of the gland was followed by complete restoration of the power of micturition, and has so far proved of permanent advantage.

The proceeding which I have thus put into practice seems first to have suggested itself to Mr. Guthrie, but I cannot find that he ever employed it; that it is not identical with the somewhat extensive incision of the prostate as for lateral lithotomy which was practised by Sir William Blizard is at once obvious. Its aim is to divide the obstruction—and the obstruction alone—by an opening so planned as not to expose the patient to undue risk; while, at the same time, it is capable of affording the greatest amount of room for manipulation by an extension of the incision, should this prove to be necessary.

I need hardly observe that a proceeding of this kind should be undertaken before the bladder has passed into a condition of confirmed and irremediable atrophy; otherwise, though we may succeed in removing an obstacle to the introduction of the catheter, our prospect of restoring the power of micturition will be as hopeless as it has proved to be under somewhat similar circumstances where the operation of lithotomy has been undertaken.

It is impossible to avoid the conclusion, from their examination after death, that many atonied bladders might have been prevented becoming so by the timely removal of the obstruction by which a condition of permanent paralysis was induced and maintained.

The operative treatment of the enlarged prostate, when it obstructs micturition to a degree that cannot be met by judicious catheterism, is yet, I believe, open to considerable improvement.

Though the literature relating to either complete or partial excision of the prostate is very limited, there is much in it of promise. In one case, where I extirpated the whole gland for malignant disease, the benefit that followed far exceeded my expectations. It was that of a middle-aged man, who, by reason of a carcinomatous prostate, was threatened with a speedy and painful death. I cut down upon the gland in the median line, and succeeded in enucleating it tolerably cleanly with my finger. I saw this patient eight months afterward in very fair health, and quite able to go about his business. So far he has enjoyed an immunity from the symptoms which induced me to perform this operation, and though his

¹ Transactions International Medical Congress, vol. ii.

¹ British Medical Journal, June 9, 1883.

disease is a malignant one, we have every reason to be content with the results obtained.

Then we have numerous examples where considerable masses of the prostate have been removed with very great advantage in the course of operations on the bladder. Amongst these I would specially mention an important case by Mr. Bickersteth; and, more recently, another by Dr. John Ashhurst, of Philadelphia, in which the whole of an enlarged third lobe was successfully removed.

Cases such as these seem to favor the hope that operative surgery will be found capable of affording more relief to exceptional instances of this kind, and of extending to the large prostate the treatment which in some degree is applicable to other deep-seated growths.

Passing to the urethra, I would again take the opportunity of adverting to the value of Otis's work in regard to the dimension and dilatibility of this canal; if he had done no more than contribute to the improvement of lithotripsy—and this cannot be questioned—we should still be largely in his debt. I cannot, however, follow him in his views relating to the performance of internal urethrotomy as a means of treating stricture of the urethra. My impression is that this operation is losing instead of gaining ground in the opinion of those who have had ample opportunities of judging fairly of its merits. That it is an operation fitted for the treatment of stricture in its early stage is a conclusion I am disposed to take exception to, on the ground that it is neither necessary nor safe as compared with other methods. I believe that the early stage of stricture may be successfully combated by the employment of thorough cleanliness combined with the judicious use of dilatation, as we are accustomed to practise it in this country.

If internal urethrotomy gave a greater immunity than other operations from a recurrence of stricture, or did away with the necessity for subsequent mechanical dilatation, then, perhaps, with the view of avoiding other risks to which all persons suffering from stricture are liable, we might feel more disposed to employ it. But as such is not the case, and the risk attending its performance is not inconsiderable, I cannot concede the importance which is claimed for it by its numerous admirers. That internal urethrotomy in some cases is a necessity—as by it we are enabled to render amenable to treatment a stricture heretofore intractable—I am willing to admit, but to recommend it as capable of effecting a permanent cure is quite another thing.

The treatment of impassable stricture of the urethra has received an important addition by the practice which Mr. Wheelhouse has introduced, the great credit of which he seems desirous rather of sharing with his surgical colleagues than of appropriating to himself, as I see he always refers to it as the "Leeds operation." Like other conditions which may be spoken of as relative to something else, rather than as fixed or defined, the impassable stricture is, I believe, gradually becoming rarer, a circumstance which is largely due to the great improvement that has taken place in the construction of instruments specially adapted to their treatment, amongst which I may mention the filiform bougies and the tunnelled instruments of Gouley, of New York. For the purpose intended, I do not think there is any proceeding equal to that which Mr. Wheelhouse has introduced, and I have no hesitation in including it among the improvements to which I am now referring.

Permit me, without apology, in this mechanical age, where invention after invention for the treatment of stricture comes upon us with marvellous rapidity, to claim a moment's consideration for what Mr. Savory has called the medical aspect of this question. We all know what irritation is: there is such a thing as irritating a stricture, either by what passes through it naturally or is introduced to correct it. Let us not disregard, as a principle of our treatment, the importance of securing for the urethra that physiological rest of which the late Hilton wrote so well.

The question may here very properly be asked whether, in our search for novelties as improvements in treatment, we have discovered any new diseases, the better management of which, by reason of our recent acquaintance with them, we may in all fairness leave to our descendants to determine. The admirable Bradshaw Address of Sir James Paget will no doubt have the effect of quickening our perceptions in this direction.

Though I cannot point to any discoveries of this kind as affecting the region which is now occupying our attention, I may note one gratifying result of extended clinical and pathological investigation: I refer to the juster assignment of symptoms to the causes producing them—symptoms which not very long ago were looked upon as constituting independent diseases. But if we have not discovered any new diseases, we must remember that varying circumstances may at one time add intensity to some disorders and considerably modify the progress of others. I have a strong impression that the times through which we are passing, characterized as they are by the production of great and continuous nerve-tension, have brought into prominence a state of brain-strain which is apt to show itself in any organ which may happen to be deranged or is overtaxed.

A recent author seemed rather to conclude that tension of this kind was most injuriously shown and felt by our American cousin, while the Britisher, for some reason or other, was less injuriously influenced in this manner. Whether this is so or not I am not prepared to decide, but I am disposed to believe that purely nervous affections—affections associated, as far as we can determine, with no obvious structural alteration—are more common than they used to be. That they occasion much distress and cause persons who suffer from them to be unduly apprehensive will be generally admitted. Nay, further, by their mimicry of more certain diseases, they induce a condition of suspense which is often intolerable. It is well, too, to bear in mind that the interpretation of symptoms, as also their prevention and amendment, are frequently to a large extent dependent on a recognition of the possible existence in a patient of exaggerated nerve-tension.

Before an audience of this kind it would be presumptuous on my part to indicate in detail the many improvements that have taken place in the treatment of the surgical disorders of the urinary organs; further, where there have been so many contributors toward this progress it would be invidious in me to particularize.

Let me, however, in common fairness, say one word in reference to the advance that has been steadily made in the construction of the appliances used for these purposes.

I can remember some instruments which five-and-twenty years ago, or even less, were then regarded as improvements, but have now passed into obscurity or to the shelves of the museum. In no department of applied mechanics has greater perfection been obtained than by the surgical mechanician, and nowhere is this better illustrated than in the instruments employed in the treatment of urinary diseases.

It seems almost ungenerous, after referring to several proceedings of an operative kind, the doing of which entail pain and involve risk for the sake of advantages to follow, that I should allow to pass unnoticed the work of those who have removed the one and lessened the other. In chloroform and anaesthetics we have a priceless boon, without which surgery would long ago have been at a stand-still, and many persons now living in comfort and enjoyment would ere this have ceased to exist. I am not old enough to remember the pre-anaesthetic age, and, therefore, am unable to draw a contrast which will be a vivid one to some of the 'elder brethren' I am addressing to-day. I am reminded, however, of an incident bearing upon such a contrast, which with your permission I will briefly relate.

Some two years ago a sea captain, a patient of mine,

and by no means a bad amateur doctor, on returning from sea, told me somewhat gleefully that he had successfully performed amputation. Whilst his ship was at Ruruta, an uncivilized island in the South Pacific, a poor native got his arm entangled in a sugar-crushing machine. As there was no doctor on the island, my friend the captain was summoned, and at once recognized the necessity for removing the shattered fragments of the limb. The shrieks and struggles of the powerful aboriginal were most fearful. Recognizing the necessity for taking steps to save the man's life, the captain hurried off to his ship, and returned with the necessary implements, and, in addition, a quart of the newest and most potent rum. In the absence of chloroform he induced his patient to swallow this fiery compound, wineglassful after wineglassful, until intoxication was induced, and subsequently profound alcoholic insensibility. Then the tourniquet was applied and amputation successfully performed. Recovery rapidly took place. So pleased was the savage with the effect of anæsthesia that he subsequently offered to let my friend cut off some of his toes provided that the process of inducing insensibility was repeated.

Next in importance to chloroform and anæsthetics are those means which have been recently promulgated for diminishing some of the greater risks contingent upon wounds and surgical operations. About antiseptics, I desire to speak in no uncertain terms. Though our views may not be unanimous, though some of us may be skeptical about the import of germs and of sprays and other details, can we doubt that when the surgical historian of the nineteenth century has to recount the men as well as the measures that have favorably influenced the progress our art has made, the name of Lister will occupy a conspicuous place?

I have now done: it has not been my ambition to hold up to you a golden calf, to attempt to dress it in flowers of rhetoric and to ask you to worship it. I have rather endeavored to remind you of some of the directions in which surgery is now travelling and to estimate in a measure the pace at which it is going. It is impossible to engage in a work of this kind without being fully conscious that though our art is an imperfect one, it is distinctly a progressive one. In the course of your visit to this, which has been aptly referred to as the second city of the empire, you will find almost all the arts and sciences laid under contribution for the development of commercial enterprise. The activity displayed in the development of trade and commerce will probably suggest the inquiry whether we are equally progressive, whether we are in correspondence with the times in which we live.

There need, however, be no hesitation in asserting that, whether we are regarded as preventers of disease, or as practitioners of surgery or of medicine, every one of us in his daily practice carries with him a proof that year by year something additional is contributed by our profession to the comfort and the life of man.

DANGER OF ERGOT IN LOCOMOTOR ATAXIA.—Dr. J. Grasset relates the case of a patient, thirty-eight years of age, suffering from progressive locomotor ataxia, to whom Charcot gave ergotine in doses gradually increased from four grains to fifteen grains daily. When the dose had reached the latter figure the patient became, with but slight warning, totally paralyzed; sensibility at the same time was markedly diminished. As soon as the drug was stopped the paralysis quickly disappeared, leaving the original trouble slightly increased. The author recalls the investigations of Tuczeck into the changes in the posterior columns in ergotism; those would indicate that ergot will not only not cure ataxia, but can even, under certain circumstances, induce sclerosis of the posterior columns. In any case, great care should be used in the administration of ergot in this disease.

ON FÖRSTERS OPERATION FOR RIPENING IMMATURE CATARACT.

By HENRY D. NOYES, M.D.,

NEW YORK.

THE rule is founded upon long experience, and is in the main sound, that a cataract should not be extracted until it is wholly opaque. So long as a patient can count fingers it is held not proper to operate. To this rule exception is made in the case of cataracts which progress with great slowness, and as they mature exhibit a deep amber or mahogany hue, or sometimes only a smoky tint and seem to have no cortical layers. Such cataracts are very hard and uniform, and never become so deeply opaque as to make it impossible for the patient to count fingers within a foot's distance. It is good practice to extract such lenses, and they generally do well. But for the commoner forms of cataract, in which opaque and transparent parts are intermingled, permitting the fundus to be illuminated with the ophthalmoscope and giving back a red reflex it is the recognized rule to postpone operating until the lens has, as the phrase is, grown ripe. The reason is that the lens separates from the capsule imperfectly, and leaves a residuum of semi-transparent material which evades expulsion and may bring on serious inflammation, either in the iris or in the capsule, or in both. Fortunately it is seldom that cataract begins at the same epoch or progresses at the same rate in each eye. Hence a patient usually has one cataract ready for removal before useful vision has ceased in the other eye. To all this good fortune does not occur.

It will be inferred that the writer approves of operating for cataract when *one* eye is fully ready for its performance. There is scarcely any dissent from this approval at the present day, provided the second eye begins to be seriously implicated in the disease. It is, however, not superfluous to call attention to this point, because the feeling exists among the laity, and to some extent among physicians, that an operation should not be done until the patient is quite blind in *both* eyes. Formerly the proportion of failures was so considerable and the rigor of after treatment was such as to make the operation a serious matter, and hence the inclination to wait for complete blindness in both eyes. As stated, the judgment of ophthalmic surgeons is in favor of operating so soon as one eye is ready, and in case the second eye begins to exhibit cataract. This is the general judgment, notwithstanding what is known respecting the occasional occurrence of sympathetic inflammation in the fellow eye.

In one eye the lens may be decidedly opaque, but the broad shadow at the edge of the pupil shows that its superficial layers are semi-transparent and sticky, while in the other eye the irritative symptoms which often attend the beginning of lenticular opacity make work difficult, although there may remain the capacity to read ordinary print. On the other hand there may be little difference in the degree of opacity in the two eyes.

Again, the patient may have lost one eye through accident, or some other disease than cataract, and in the remaining eye lenticular changes have begun.

When the patient can no longer do fine work, such as sewing, or writing, or reading ordinary print, or cannot follow his occupation, he may for months or years retain vision sufficient to count fingers at one foot. During this period he can feed and dress himself, and may walk about in safety. But he finds his situation most trying. The great trouble is want of occupation, and many complain bitterly of the tedious idleness which they have to endure.

It will be readily appreciated that weariness of mind may act unfavorably on the state of health, and inasmuch as predictions as to the rate of progress of cataract cannot be made with any definiteness we leave a patient small consolation when we tell him it is better to wait

for the lens to ripen, than to take the risks of failure by a premature operation.

It was once a common practice, now less frequently resorted to, to perform iridectomy some weeks prior to extraction, to diminish the risks of the operation. I have noticed that immature cataracts appeared to grow opaque more rapidly after the iridectomy than they did before. This incidental effect has not been kept in view as an indication for the operation, but it deserves mention.

It has been proposed to bring about full opacification of cataract by discission of the capsule with a needle. It would appear that this proceeding might justly be employed in view of the experiences of the late Mr. Jacobs of Dublin, who favored the treatment of senile cataracts by discission alone. But surgeons have seldom adopted the needling operation either to ripen or to cure senile cataract. As a means of cure the proceeding calls for too much time, as a method of ripening cataract. It is apt to be ineffectual and as I have verified by experience it is not devoid of danger.

Mooren ("Fünf Lustren Ophthalmologischer Wirk-samkeit," 1882, page 207) gives his experience on this point to the following effect. That in all cases of arterial sclerosis, and whenever there is undue tension of the globe, no operation for artificially ripening cataract should be performed. If done, glaucomatous complications will be almost certain. In other cases Mooren resorts to the following method. An iridectomy is first made, and the greatest care must be given to the avoidance of pupillary adhesions afterward. About three weeks afterward he opens the capsule, not with a needle but with a Graefe's knife for about three-fourths its diameter from above downward, and takes the utmost pains to avoid luxation of the lens. For two days the patient is kept in bed. Ripening ensues in from a few days to a few weeks, according to the quality of the lens. Great respect is due to Mooren's opinions on such a subject, because he has had an uncommonly large experience with cataract. He reports (p. 211) having performed two thousand three hundred and thirty extractions by what he calls the scleral incision. It is also to be said that the technical skill and the judicial capacity which he possesses will greatly surpass what ordinary operators can claim.

It is to be desired that the least danger should be incurred in all operations in the eye, and the method of artificially maturing cataract now to be described seems worthy of cultivation.

Within two years Professor Förster, of Breslau, Germany, has published an account of a method for bringing about the maturity of cataract which seems worthy of imitation. His proceeding was made known to the Ophthalmological Congress of Heidelberg in 1881, and afterward announced in the International Congress of London in 1882. He has also written about it in *Archives of Ophthalmology*, vol. xi., No. 3, p. 344, 1881. He performs iridectomy upward, and while the anterior chamber is empty strikes or rubs the cornea with the convexity of the iris forceps or with the convex portion of a strabismus hook. In doing this rather firm pressure is made upon the lens as it now lies against the cornea, and the friction is chiefly confined within the area of the pupil and of the coloboma. The manœuvre is similar to that commonly employed for expelling blood from the anterior chamber, but the pressure is deeper. Necessarily care must be taken not to dislocate the lens and not to cause prolapse of vitreous. The instrument which I have employed in all cases but one has been a Daviel's silver curette or a narrow spoon of hard rubber.

The movements are mostly in a rotary direction, and are continued for perhaps a minute, but I cannot pretend to say for how long time they were kept up, any more than I can tell how much pressure was employed. (The manœuvre has been entitled trituration of the lens, but this surely is a stronger word than the facts warrant. It were better, perhaps, to speak of it as massage or compression.)

My experience extends to eight cases, which are summarized in the following table:

No.	Name, sex, age, date of operation.	Duration and incidents of treatment.	Period of maturity.	Extraction of cataract—incidents.	Result—vision.
1	Mrs. S—, female, 68, March 23, 1882.	Five days, slight iritis.	Three months.	October 10, 1882, ten days, Graefe, normal.	V = $\frac{3}{10}$ +.
2	Mrs. Meta J—, female, 70, April 14, 1882.	Seventeen days, severe.	Three months.	July 14, 1882, Graefe, severe iritis, forty-three days, normal.	After iridectomy, October 29, 1882, V = $\frac{7}{10}$.
3	Mrs. Ellen McC—, female, 70, May 5, 1882.	Seven days, normal.	Five days.	October, 1882, Graefe, normal, eighteen days.	V = $\frac{4}{10}$.
4	Patrick C—, male, 45, May 19, 1882.	Ten days, normal.	Two months.	July 14, 1882, Graefe, normal, fourteen days.	V = $\frac{3}{10}$.
5	Matthew T—, male, 62, October 20, 1882.	Five days, normal.	One month.	November 24, 1882, Graefe, normal, fourteen days.	After two cystotomies V = $\frac{3}{10}$.
6	Mrs. Meta J—, female, 71, February 16, 1883.	Seventeen days, considerable reaction, but no iritic adhesions.	Three months.	May 28, 1883, twenty-nine days, mild iridocapsulitis.	Thin membrane in pupil—awaiting operation—V = $\frac{2}{10}$.
7	Mrs. Mary S—, female, 61, May 18, 1883.	Seven days, normal.	One week.	June 30, 1883, eighteen days, normal.	Thin membrane in pupil—awaiting operation.
8	Thos. McC—, male, 70, May 25, 1883.	Seven days, normal.	Three weeks.	Extraction not performed.	

In all cases the subjects were above sixty years of age. Four were females, three were males. In one female both eyes were operated on at an interval of ten months. In this patient alone did any serious reaction take place—and this occurred in both eyes, and at both operations for ripening, and also at the extraction of the lenses. When her first eye was operated on severe iritis followed Förster's method (Case 2), and numerous posterior synechiæ occurred. The extraction was done three months later, and was not as normal in its performance as I could have wished. For this reason, as well as because of the irritable condition of the eye, the healing occupied a long period (forty-three days), a dense membrane formed in the pupil and iridectomy became needful. The ultimate result, V = $\frac{3}{10}$, was good. The patient desired to have the other eye treated, and better fortune attended the operations, but it was evident that she was unusually prone to inflammatory reaction. The result in this eye is yet incomplete, because a thin pupillary membrane remains to be divided (Case 6). In one other case, viz., No. 1, iritis, with few synechiæ took place, but no prejudicial effect was thereby produced. The period of confinement after Förster's operation varied from seven to seventeen days, the average was 9.4 days. In one patient, Cases 2 and 6, cataract had for four years been in the stage which prevented "working" sight. In other patients the period which had elapsed since they could see to work was from a few months to a year. The exact period was not always obtained.

The time required to mature the cataract varied from five days to three months. The long period occurred in two patients, viz.: in Case 1 and Cases 2 and 6. The latter, who had the most severe experience, had cataracts which were devoid of all cortical opacity, and the ripening process was slow. Cases 3, 5, 7, and 8 had abundant cortical opacity, and the effect in them was prompt and without unpleasant reaction. In none of the cases did the lens seem to swell or did any glaucomatous symptoms arise. It would not be prudent to say that such mishaps might not take place, the presumption is that swelling of the lens would occur, and if so, glaucomatous complications would be expected. It is, however, safe to state that such accidents are far less likely than after Mooren's method of incising the capsule.

It will be observed that in no instance was the extraction done sooner than two months, while in some cases it was not done until six months after the accelerating iridectomy. The postponement was not in all cases because of unreadiness of the cataract. An increase in opacity was in all cases noted as ensuing immediately, but the rate of increase was not always alike. It did not show itself chiefly upon the anterior surface of the lens, but seemed to come up from the deeper layers. It did not appear to depend on direct disintegration of the lens-fibres or of the capsular epithelium, but rather it may be conjectured, on disturbance of the suspensory ligament. It was much more regular and evenly distributed than the opacity which takes place after a traumatic interference, by a needle or by a foreign body.

It is too much to expect of an operation that it should never present a shady side, and this larger experience will doubtless bring out. I have heard a case verbally reported which was followed by irido-cyclitis and loss of the eye, and we know that iridectomy alone is sometimes followed by loss of the eye. I have stated that, in two of my operations there was some reaction on the part of the iris. It follows that the operator must not venture with a heavy hand, and must confine his friction to the centre or the cornea, while the moderate experience already collected indicates that Förster's proceeding merits further trial.

ON THE TREATMENT OF NON-SPECIFIC ULCERS OF THE LEG.¹

By SMITH BAKER, M.D.,

WHITESBORO', N. Y.

To engage successfully in the treatment of ulcers of the leg, whether indolent or irritable, requires a most exact appreciation of the system as well as the local condition.

General or specific debility from any cause, near or remote interference with the local blood-supply, irritation of the nerves proceeding to the part, mechanical or chemical irritation of the part itself, are all important factors in the etiology of cutaneous ulceration, and are just as important in retarding progress toward recovery.

Writers upon this subject generally recognize this more or less, as a cursory survey of the more recent literature reveals.

Thus, whether it be Christopher Heath's² opium, arsenic, and potassium iodide treatment; or the skin-transplanting and grafting plan of Drs. Hamilton³ and Bryant;⁴ or the subcutaneous resection of the irritable and irritating nerve, as taught by Mr. Hilton;⁵ or the local application of emollient and nutritive substances, as suggested and practised by Dr. Cowen;⁶ or Mr. Holt's⁷ plan of removing all hypertrophic tissue, elevating the leg, sealing hermetically, and attending strictly to the general health; or that of Dr. Braithwaite,⁸ which consists in applying lead lotion, plus a small proportion of carbolic acid,

and exposing several hours to the air; or the exercise, poultice, chalk and lard treatment of Dr. Spender;¹ or that by Dr. Mandelbaum² by scraping the surface, applying iodoform, and following with equal parts of mercurial and soap plaster; or the pure-rubber bandage treatment of Dr. Martin; or the combination of the latter with the local application of liquor carbo-detergens, as carried out by Mr. Hutchinson;³ or the use of a saturated solution of potassium chlorate, as advocated by Dr. Rochester; there is in each an attempt to apprehend the etiology as well as the indications for treatment.

Yet many general practitioners seem to fail in this respect. They apparently forget that the application of caustics when the system is already debilitated, the giving of tonics when there is every evidence of good health save the local affection, the effort to secure resolution by attention to the special locality where the nervous or circulatory system is at fault, is in each case an endeavor to accomplish the impossible.

This is suggested by reference to one of my earlier cases.

CASE I.—A buxom, hardworking widow, aged forty, mother of five children, and of no particular constitutional taint, received a blow on the inner aspect of the right leg, which in five weeks after had resulted in an ulcer $2\frac{1}{2} \times 4$ ctm., having a dry surface, and so sensitive as not to allow of the application of the softest poultice. A weak lotion of carbolic and hydrocyanic acids, glycerine, and water, freely applied and covered with oiled silk, relieved the pain at once, and by touching edges with silver nitrate and painting vicinity with tr. iodine, healing to the extent of one-half was secured in twenty days, and nine-tenths in twenty days more. At this point, however, it resisted all efforts until the fourth month, when it healed of itself.

Now in this case there were three months required, three-fourths of which time was lost time simply because bandaging was not adopted and the slight œdema of the adjacent subcutaneous connective tissue kept down—thereby relieving the skin tension, and permitting a reparation of the local nutritive processes. This case may be contrasted with the following:

CASE II.—An unmarried, scrawny woman aged forty, with catamenia still regular, a hard-working weaver, had, during most of the time for eighteen years suffered from an ulcer of the left leg, with a thin edge and irritable surface, and quite as much from the different plans of treatment proposed and carried out by many doctors. Five applications of galvanism (positive pole to the ulcer) plus the alternate use of potassium permanganate and potassium chlorate lotions, and the daily wearing of a well and snug-fitting elastic stocking soon enabled her to assume her duties, and secure a healed leg in addition.

The indications to clean and support the part, and to encourage a better nutrition, were here met as the result attests.

CASE III.—Married woman, aged forty-nine, housewife, mother of several children, who at the age of fourteen suffered a severe strain and some injury of the lumbar region, which was treated *by two years in bed, sixteen setons, and innumerable blisters to the back!* Since then she has had a frequently recurring, irritable ulcer on the right leg, which is always preceded by pain in, and tenderness over, the lumbar vertebra, and frequently by pain in left ovarian region, with dysmenorrhea and profuse leucorrhœa. These ulcers have always defied the efforts of the neighborhood surgeons, and after long sieges have healed of themselves. She came to me with a recently ulcerated surface of 8 ctm. in diameter, surrounded extensively by eczema, and which had been preceded as usual by several weeks of backache. The use of ergot and potassium bromide internally, and of a weak carbolic acid lotion externally, secured resolution in about three weeks. This case seems to show, as

³ Medical Abstract, 1877.

Charent¹ says, "there is nothing better established in pathology than the existence of tropical troubles consequent on lesions of the nervous centres or of the nerves."

CASE IV.—An Englishwoman, aged ninety-three, the last child of a consumptive family, the mother of seven children—two of whom were delivered with forceps, and all but one of whom have died of tuberculosis—herself a lifelong sufferer from neuralgic troubles, also from severe deafness for fifty years, and from complete prolapsus uteri for forty years, had at the age of seventy-six a severe illness, which was followed by a three years' standing ulcer of the left leg, which at the end of this time healed spontaneously. Five years after she took to crutches (aged eighty-four), but otherwise enjoying her usual health. Two years ago she accidentally injured the inner aspect of the left leg, and got, in due time, under domestic care, as a result, a large, irritable, indolent ulcer, which resisted all treatment for weeks, but finally healed under the use of salicylic acid in vaseline. Nine months since, however, it broke out again, and after three months was found to be $3\frac{1}{2} \times 6\frac{1}{2}$ cm., and so sensitive that a breath of air caused intense suffering. An attempt to use a Martin bandage was hopelessly frustrated by her whimsical repugnance to its use. A severe prostration from diarrhoea supervened, and after this for weeks, although a multitude of plans were faithfully tried, there was no progress toward recovery. Finally, by simply alternating a lotion of potassium permanganate with one of potassium chlorate, the ulcer has, three months since, entirely healed.

In this case the extremely low vitality and interference of the patient nearly negated all efforts at treatment. The result under the circumstances may be considered a happy one.

And it is equally true that lowered vitality from any cause may favor the development of any case of non-specific ulcer of the leg; while subsequent irritation, whether from mechanical or chemical sources, may be the means by which the cutaneous necrobiosis is kept up.

Hence treatment may be considered as properly consisting of giving tonics when needed, and especially will galvanism, phosphorus, and strychnia be found indicated in a large proportion of cases; or of allaying nerve-irritation or irritability by exhibiting opium, potassium, bromide, or ergot; and of attending strictly to hygiene, which includes specifically cheerful surroundings, *exercise*, and good food.

As regards local treatment, there are only two important indications, namely, cleanliness and protection.

For what do the various lotions and applications more than to clean the sore of the discharge that has become decomposed and consequently irritating, and to prevent further decomposition from taking place? and what does the bandaging or strapping more than to protect the sore from engorged blood-vessels and oedematous adjacent tissue, or from external irritants of all kinds?

Hence what can be better for local treatment than to order the surface cleansed thoroughly at bedtime with a weak solution of potassium permanganate, also in the morning with a medium solution of potassium chlorate, and after having covered it lightly with absorbent cotton, to have drawn on over all a *well and snug-fitting* elastic stocking, with instructions to go about the usual labor using the limb freely but not senselessly? At any rate, in nine-tenths of cases this, according to my recent experience, seems to be all-sufficient; while in the other one-tenth a few days rest and preliminary treatment with the same lotions and a pure-rubber bandage seems to be equally necessary.

This plan of treatment is simple, and perhaps not convincing. But I am satisfied that in this plan lies the disposal of the whole class of non-specific ulcers, securing a minimum of suffering and loss of time to the patient, and a maximum of credit to the profession.

THE TREATMENT OF CHRONIC BRONCHITIS.

By T. J. YOUNT, M.D.,

LAFAYETTE, IND.

"WINTER cough" has been known for untold centuries. Nebuchadnezzar no doubt had this disease, for the physicians after dosing him with villanous decoctions, nauseous infusions, and diabolical extracts, turned him out to grass. They did not find a single specific or panacea in all the medical literature of their forefathers for chronic bronchitis. The chronic bronchitic then, as now, was a victim to be pitted.

During the winter and spring months he sits in the house, in a snug corner near a roaring fire, huddling together his skin and bones lest they get separated and lost. He sits there in his corner with his cuspidor handy, morose, dejected, and irritable to those around him. His face is pinched and his color yellow, he eats little and sleeps less, worried and worn out with cough. In the summer, like the ground-hog, he comes from his hole, wrapped up in a thick ulster with fur collar, and cap drawn down over his ears, and his feet encased in large arctic overshoes. He walks slowly and swears rapidly at his ill-luck in having such a disease. He likes to tell how he feels and gives all the blame for his illness to the weather and his liver.

The chronic bronchitic, like the white corpuscle, is of a very migratory character, migrating from one physician to another and travelling from one end of the earth to the other. It is seldom that you see a patient that has not been treated by at least half a dozen physicians, and he rarely tarries long with any one, but seeks new fields and medicines. In the treatment of this disease we must support our patient, ease cough and pain, promote digestion and appetite, and render substantial aid during an acute attack.

Suppose, now, you are called to see a patient during an acute attack, where there is a swollen condition of the bronchial mucous membrane, with scanty secretion, harassing cough, urgent dyspnea, and great pain. He sits upright, face livid, pulse weak and rapid, and the respiration shallow and frequent. He begs in Heaven's name for a moment's relief—for just five minutes' rest and sleep. You have all seen him.

Relieve this sufferer now and he is your life-long friend and patron. You must act, and act promptly or all is lost. You are like the man in Texas, who, when he wanted a revolver, wanted it *awful* bad. Just so with you: you want to help the patient, and you want to help him very bad. Suppose you give him a dose of morphine, that would surely ease him, but the probabilities are that it would be permanent, and you could no doubt next day read his obituary notice. Opiates act first on the hemispheres, by dulling their sensibility; this dulling of sensibility extends to the medulla oblongata, which becomes paralyzed and your patient dies, simply because the carbonic acid in the blood fails to irritate this centre of respiration and have it call on the expiratory muscles to assist in throwing off this accumulated carbonic acid poison. If it is, therefore, not safe to give opiates or chloral, what will you give? We must rely on respiratory stimulants, good ones that will not fail us. There are three well-known stimulants that are considered perfectly reliable and potent, viz.: ammonia, strychnia, and belladonna. Of the preparations of ammonia, I prefer the aromatic spirits, or the carbonate. In very serious cases, twenty drops of the aromatic spirits, or ten grains of the carbonate, with twenty drops Squibb's compound spirits of ether, given hourly or every half-hour, affords great relief. If the heart is feeble and rapid, ten drops tincture digitalis should be added once in two hours. If they are nervous and want rest, give bromide of ammonia in one-half or one drachm doses as often as is needed. Rokitanski first found that strychnia was a potent respiratory stimulant. T.

Lauder Brunton, J. Milner Fothergill, and H. C. Wood have long recognized strychnia as a very reliable and rapid stimulant. Fothergill, in severe cases, gives as large as one-tenth grain doses of strychnia every four or five hours, and oftener if necessary. He says desperate cases demand desperate remedies. His favorite prescription for ordinary acute attacks is :

R. Ammon. carb. gr. v-x.
Tr. nucis vom. ℥ x.
Tr. scillæ. ʒ ss.
Infus. serpent. ʒ j.
M. et sig.—Take every three or four hours.

He adds ten minims tincture digitalis to this mixture if the right ventricle is weak. Belladonna is also a reliable stimulant. It is of special value where there is general want of tone, giving rise to profuse night- and day-sweats. You have all given atropia for night-sweats of phthisis, and you have noticed that the patient, while benefited by the arrest of the sweats, was also greatly benefited in his breathing, breathing less rapidly, taking deeper breaths, and less dyspnoea in walking about. In some cases where it is absolutely impossible to get relief from severe pain in the side by other means than opiates, give atropia, and morphia combined.

I have often given persons suffering from a mild attack of chronic bronchitis the muriate of pilocarpine, in one-tenth to one-twenty fourth grain doses, every hour or two with great benefit. It has many advantages over ipecac and squills. It is pleasant to take and does not nauseate. It is very prompt in loosening the phlegm, distressed breathing, and annoying cough. It has a decidedly stimulating action on the skin, mucous membranes, heart, and kidneys. Fothergill's father always taught him "never to give squills until the skin is moist and the phlegm loose, and always to give ipecac as long as the skin was hot and phlegm tough." If such is a safe rule, and Fothergill says it is, then we ought to use pilocarpine in all acute stages of disease of the bronchial mucous membrane with great advantage. Inhalations and sprays may often be used with benefit. I have derived the most benefit in my own case from sprays of benzoate of soda, ten to twenty grains to one ounce, followed by prolonged sprays of compound tincture of iodine, ten to thirty or forty drops to one ounce. These used in this manner three times a week generally result in a decided arrest of the profuse secretions and start up a healthy action. Sprays of nitrate of silver, carbolic acid, tannic acid, potassæ chlorate, and zinc sulphate can be used, either in sprays or inhalations, with benefit where the secretion is too profuse. The application of irritating liniments and solutions often scatter and relieve pains like magic. My favorite application is :

R. Tr. iodini. ʒ ss.
Ætheris sulphurici. ʒ ij.
Ol. tiglli. ʒ ij.
M. et sig.—Apply as directed.

Where the patient is suffering from an acute pain in the side and is feverish and nervous the application of an ointment composed of acidi salicylici, ʒ ij.; morphia sulph., gr. j.; acid. oleici, ʒ j.; adeps, ʒ ss. should be made.—Applied three or four times a day or oftener, until relief is afforded. By this application you avoid giving opium by the stomach, which as a rule destroys the appetite, impairs digestion, and renders the liver inactive by arresting the normal secretions and perverting their healthy action. In cases of chronic bronchitis, where the secretions are scanty and dry, full doses of iodide of ammonia, say of twenty grains, three times a day. By combining the iodide of ammonia with copaiba, cubebs, encalyptol, or arsenic you produce a decided effect upon the secretions, often arresting them and having a decided curative action. The liver should also be looked after in this climate, and its action should be assisted by an occasional dose of calomel, podophyllin, or elixir wahoo.

Quinia in tonic doses, taken for weeks, is of decided benefit. Fellows' compound syrup of hypophosphites, containing, as it does, quinia, with potent nerve-tonics, is a valuable preparation.

Gardner's syrup of hydriodic acid, a non-irritant preparation, containing it is claimed, ninety-nine per cent. of iodine, has a decided curative effect on this disease. I have used it on myself and many patients, and have experienced almost immediate benefit by the arrest of the profuse secretions and cough. The only objection to it is the strong and pronounced metallic taste which invariably follows its prolonged administration, causing loss of appetite and consequent debility.

It should be given in teaspoonful doses three times a day at the commencement, and gradually increased to two or three teaspoonfuls three times a day well diluted in Burgundy wine, porter, or water. In my own case I have had the most prompt and decided benefit from Declat's syrup of nascent phenic acid. It is pleasant to take, and its action has in my hands been very pronounced. It should be given in larger doses than the directions on the bottle. I experienced no benefit until I had taken six drachms three or four times a day. Under the six-drachm doses in one ounce of whiskey or a wineglassful of Hoff's malt, my light, harassing cough was relieved, the exhausting night-sweats ceased, the appetite improved, and sleep was rendered natural. In fact, under ten days' administration of the acid, more rapid and permanent improvement was made than ever before in any previous attacks. Its administration in such large doses should not be persisted in longer than two weeks at a time: then it should be suspended a week or ten days, and commenced and kept up as before, gradually lessening the dose as the disease disappears. I have often prescribed this syrup in obstinate coughs where relief was not obtained by the ordinary remedies, and have had good results.

To obtain good results you must give the syrup of the nascent phenic acid, and you must give it unsparingly. You will get no appreciable results from half a tablespoonful, and may be compelled to give it in two tablespoonful doses. In cases where there is great debility and no appetite, great advantage may be obtained from taking frequent egg-nogs or milk punches. These may often be preceded by a wineglassful of Hoff's fluid malt, etc. When there is great despondency and nervous prostration, decisive advantage may be had from ext. cannabis ind., gr. ʒ-j.; ext. hyoscyam., gr. ij.; quinia sulph., gr. ij.; taken three or four times a day. The sleeping-room and bed should be warm on arising and retiring, for the reason that the chill from getting into a cold bed and getting up in a cold room gives rise to severe and prolonged coughing. It is also a good idea to take a good alcoholic night-cap before retiring, as it tends to produce sleep and quietude. Patients with chronic bronchitis should not take alcoholics before going out into the cold air, for the reason that alcohol dilates the capillaries in the skin and makes the patient more liable to take cold. If he wants a drink let him take it after he comes into the house. He should wear flannel underclothes the year round, and during the cold and changeable weather should wear a chest-protector.

It is advisable that the patient should take a trip to some equable and mild climate, such as San Antonio, Los Angeles, Aiken, S. C., or New Mexico, during the cold spring and winter months. New Mexico is to be preferred above all as the sanitarium of the world for lung and bronchial disorders. Let he who doubts this statement go and see for himself, and he will return a healthier and better man.

The Creator in his all-wise and all-powerful mind saw that sufferers from chronic bronchitis needed a special habitat, he therefore gave unto the world and the sufferer the United States, because it had New Mexico in it, that one State created for no other purpose than invalids.

Progress of Medical Science.

PAGET'S DISEASE OF THE NIPPLE.—Dr. Duhring reports in the July number of the *American Journal of the Medical Sciences* two cases of Paget's disease of the nipple, which he holds is not an eczema, but a peculiar disease with a malignant tendency. It must be distinguished from eczema, which it resembles, and from ordinary cancer, which it is altogether unlike in its earlier stages. It seems to occupy a ground having the characters of both diseases. The report is interesting as showing the natural history of the affection. This is peculiar. The course of the process is emphatically chronic. In both instances, moreover, the progress of the disease was insidious as well as slow. Nothing of a malignant nature was suspected until after the lapse of five and ten years respectively. The itching, which eventually became such a marked symptom, was in both cases insignificant until the affection had existed several years. It may be said not to have manifested itself until after the process had been well established. In this respect the disease differs decidedly from eczema, where itching is one of the first signs noted. The circumscribed, sharply defined outline of the lesion, and the slightly elevated border, are also symptoms which do not obtain in eczema. The brilliant color of the lesion is striking, and is more marked than in eczema. The absence of the "eczematous surface," characterized by appreciable discharge or by vesicles, pustules, or puncta, coming and going from time to time, and the absence of exacerbations, so usual in eczema, may also be referred to. A point to which attention may also be directed is the infiltration, which is firm or even hard, but is not deep-seated. It is rather superficial. In eczema, on the other hand, it is soft. The pains coming on later in the course of the disease, and the indurated, lumpy, or knotted lesions within the gland structure, of course point strongly to the malignant or cancerous nature of the disease, the existence of which cannot be doubted.

CHAUFFAGE OF THE GENITAL ORGANS IN VENEREAL DISEASE.—Following in the line of Chauveau's experiments in weakening virus by heat, Dr. Aubert suggests that the virus deposited upon the skin or in the tissues may be modified by raising the temperature of the part to 108° or 109°. He remarks upon the cure of paronychia sometimes obtained by immersing the finger in hot water, and suggests that we might avert by this means the consequences of snake-bite, dissection wounds, or a suspicious coitus. M. Aubert has made a few experiments in this direction with chancroidal pus. He exposed a part of this pus for twelve hours to a temperature of about 109°, while the rest was preserved at the ordinary temperature. Inoculations with the warmed pus were without result, but a chancroid followed the introduction of the other. He therefore concluded that chauffage destroyed, or at least rendered innocuous the chancroidal virus. The author has as yet made no experiments with the virus of syphilis or gonorrhoea. He suggests that the high temperature is the explanation of the subsidence of syphilitic manifestations during the course of typhoid fever or other febrile disease. He further asks if the fact that chancroid is not developed in the interior of the body and never passes beyond the superficial lymphatic glands, may not be explained by the destruction of the virus by the heat of the deeper tissues. —*Journal de Médecine de Paris*, June 2, 1883.

HYDATID CYST IN THE BICEPS MUSCLE.—The following case, only three similar ones having been previously recorded, is reported by Dr. Picqué (*Journal de Médecine de Paris*, May 26, 1883): A woman had noticed a tumor on the anterior part of her left arm for about ten years, but it was of small size and never occasioned any pain or inconvenience. Suddenly, about two months be-

fore the patient came under observation, the tumor began to grow rapidly until it had attained the size of a child's head. It was elastic, fluctuating, of regular contour, movable upon the subjacent tissues, and not adherent to the integument. The humerus was unaffected, the radial pulse was normal, and sensibility was but little changed. There was no pulsation in the tumor, nor any other sign of aneurism. The axillary glands were not enlarged. The diagnosis lay between a cold abscess, a hæmatoma, or a hydatid cyst. Upon puncture of the tumor a quantity of pus was evacuated in which were found the characteristic hooks. The treatment consisted in a free incision, followed by scraping the walls of the cyst with a sharp spoon, and was successful in its results.

PERIODICITY OF CERTAIN SYMPTOMS IN HEPATIC DISEASE.—Dr. J. Cyr (*Journal de Médecine de Paris*, June 2, 1883) says that although various writers have remarked upon the periodicity of some particular important symptom (pain, jaundice, vomiting, etc.), in disease of the liver, the observations have been isolated and so few as to attract little notice. He has collected upward of forty cases, occurring in his own practice, in which some symptom, usually pain, presented a more or less marked intermittency; often the same symptom returned with most striking regularity. This periodicity was peculiar, in that it was in most cases uninfluenced by quinine, but disappeared under treatment directed to the hepatic disorder. From these observations he draws the conclusion that the periodical element in hepatic symptoms has a greater importance than has hitherto been attached to it. And he states that often in doubtful cases, as has occurred in his own experience, the determination of the fact of intermission in one or more of the symptoms may be of great value as an aid to diagnosis.

CONTUSIONS OF THE BRAIN AND SPINAL CORD.—The late lamented Dr. John A. Lidell, in an elaborate paper on this subject in the *American Journal of the Medical Sciences*, July, 1883, discusses the clinical history, diagnosis, prognosis, and treatment of this large and very important class of injuries. While much is said in our text-books on the subject of cerebral concussion—of its dangers and of its importance—but small if any mention is made of the contusions of the brain which so very often complicate the concussions, and impart to them whatever of gravity, be it much or little, that they may chance to possess. And still less mention is made of the contusions of the spinal cord. No wonder, then, that bruises of the brain-structure and of the spinal cord substance occur much more frequently than is generally supposed, that the relationship which exists between these injuries and concussions is not well understood, and that the bruises of these organs often escape even all suspicion during life. That slight or even moderate concussions of the brain sometimes, perhaps not unfrequently, occur without being complicated with contusions of the brain, the author does not doubt. Contusion of the brain is, therefore, he believes, not synonymous with concussion of the brain; but, at the same time, all the evidence now collected tends to prove that the severe instances of cerebral concussion are always complicated with cerebral contusion. Concussion of the brain, however, derives its chief importance from the fact that it is very often associated with contusion of the brain; and, in examining a case of cerebral concussion, the question of most importance for the surgeon to decide is whether or not cerebral contusion is also present. These are points of doctrine which practically have much interest for patients as well as practitioners, because of the influence they are likely to exert in the direction of procuring a correct diagnosis, and, consequently, a wise treatment. For in the disorders of no other parts of the body is it more true that an accurate diagnosis begets a wise plan of treatment than in those of the brain and spinal cord.

CHANCER OF THE TONSIL.—The following case is reported by Dr. Hue in *La France Médicale* of May 31, 1883. A man, thirty-seven years of age, of unusually good health, had complained for about six weeks before admission to hospital of slight pain upon the right side of the throat in swallowing. This pain gradually increased in intensity, and at the same time a swelling appeared in the right submaxillary region. He did not trouble himself much about it, but continued to work as usual; soon, however, he began to have poor nights, he was troubled with headache, had fever, a general feeling of malaise, and sometimes slight vertigo. Upon the right tonsil was seen an ulcer about the size of a ten-cent piece, with sharp-cut edges, marked by a red border with a yellowish-gray centre of irregular surface, emitting a sanious discharge. The tonsil was enlarged, and indurated about the base of the ulcer. There was a characteristic agglomeration of the maxillary glands upon this side, of about the size of a pigeon's egg, but varying according to the conditions of repose and external warmth. The cephalalgia was more violent during the night than during the day, and occupied only the right side of the head. The diagnosis wavered for a time between epithelioma and chancre, but was finally settled upon the latter. Appropriate treatment was pursued with some benefit, but without success in preventing the appearance of secondary symptoms.

SUDDEN DEATH AT THE BEGINNING OF CHLOROFORM INHALATION.—Dr. Janovitch Tschainsky relates in *Medizinische Westnik*, Nos. 12 and 13, 1883, the case of a peasant, twenty-eight years of age, upon whom he was about to operate for the removal of a lupoid growth from the under lip. Hardly had the patient taken two whiffs of chloroform when respiration ceased and he was dead. The necropsy revealed fatty degeneration of the wall of the right ventricle, while that of the left appeared to be normal. The reporter attributed the death to psychic causes, the dread of the operation. He relates several similar cases, among which was that of Cazenave. In this case the surgeon desired to operate upon a very nervous patient without chloroform, and in order to deceive him held a bag of pure air before his mouth; he breathed four times and died. Desault, being about to cut for stone, drew his finger-nail across the perineum to indicate the line of incision. The patient in his alarm gave a shriek and died.

THE FEEBLE INFLUENCE OF IODINE OVER MALARIAL FEVERS.—There have recently appeared numerous reports from medical men in various parts of the world, reciting the virtues of iodine in the treatment of malarial fevers. It is true that these do not all agree as to the exact degree of reliance that may be placed on this agent as an antiperiodic. There are, however, those who claim for it an efficacy not less than that of Peruvian bark, as far as the immediate control of the attack is concerned, and even greater than bark in preventing its recurrence. It must be confessed, however, that the results reported by various observers do not entirely agree. Here we find an assertion that in chronic malarial poisoning iodine does its work most effectually; there, that its value is nil; in another article we find that it is recommended to render permanent the cure that quinine has begun; in still another, that it is given in combination with quinine, arsenic, etc. On the other hand, we find that by some, antiperiodic properties are denied to iodine. Attracted by the testimony in its favor, and with the desire to definitely ascertain the powers of iodine as an anti-malarial remedy, in view of the ease of its administration and of its comparatively small commercial value, Drs. J. E. Atkinson and Hiram Woods availed themselves of the opportunity of treating malarial fevers afforded at Bayview Asylum, Baltimore, during the late summer and autumn of the past year (1882), and they record the results in the July number of the *American Journal of the Medical Sciences*. Their experi-

ence leads them to draw the following deductions as to the use of iodine in acute malarial poisoning: 1. In intermittent fever it has some feeble influence in controlling the paroxysms. 2. It takes usually from three to eight days to exercise this influence. 3. In cures effected there is great danger of a relapse; certainly as great as with Peruvian bark. 4. It is certain to add to any existing diarrhoea or nausea, and is liable to cause each if they do not already exist. 5. In remittents, its effect, if any, is seen in a slow and gradual reduction of temperature, and this reduction is liable to sudden interruptions. 6. In both forms of malarial fever it is infinitely inferior to either cinchonidia or quinine: certainly as regards the immediate control of the fever, and as far as we are able to judge, as regards relapses also. 7. From an economic point of view, the slowness and uncertainty of its action makes its use in hospital practice fully as expensive as Peruvian bark. 8. There seems to be ground to believe that it can cause albuminuria. 9. In the large majority of cases of ordinary acute malarial poisoning it has no influence whatever.

CONGENITAL CARDIAC CYANOSIS.—The following case was reported to the Société Anatomique de Paris by Dr. Toupet (*Le Progrès Médical*, June 9, 1883). The patient, seven years of age, had been the subject since birth of cyanosis. The face and extremities were blue, the eyes prominent, and the nails enormously hypertrophied. The temperature was 96.5°, the respiration rapid and labored. The heart was greatly enlarged, and a loud blowing murmur with the first sound was audible at the level of the third costal cartilage near the left border of the sternum. During the four years that it remained under observation the child passed safely through measles and whooping-cough, but finally died in an attack of pulmonary congestion. Upon opening the chest the heart appeared to lie nearly in the median line, owing to the greater size of the right ventricle. The right auricle was of normal size and well formed, while the left was merely rudimentary. The aorta was greatly dilated up to the origin of the left subclavian artery, where it resumed its normal dimensions. The pulmonary artery was seen alongside of the aorta and only about one-fourth of its size. The walls of the right ventricle were very thick, the tricuspid valve seemed healthy. The infundibulum was separated from the right ventricular cavity by a sort of partition pierced by an opening the size of a small goose-quill. The mitral valve was normal. The interventricular septum presented a solution of continuity at its upper part large enough to admit of the introduction of a finger. The aorta arose exactly at the septum, opening into both ventricles. The valves in the inter-auricular septum closing the canal of Botal were not adherent, and were pierced also by two openings the size of a crow-quill. The lungs were congested but presented no trace of tubercles.

ENLARGEMENT OF THE BRONCHIAL GLANDS AS A CAUSE OF IRRITATION OF THE PNEUMOGASTRIC NERVE.—Dr. Edward T. Bruen, in the July number of the *American Journal of the Medical Sciences*, discusses the effects of enlargement of the bronchial glands in producing reflex irritation of the pneumogastric nerve. The difficulty in the diagnosis of such cases consists in separating them from cases of early phthisis. One must rely mainly on the absence of the combination of physical signs required to render the presence of incipient phthisis certain. These are impaired percussion resonance, some form of bronchial breathing, possibly fine moist râles and increased vocal resonance. The last two physical signs are not present in cases of bronchial enlargement. Pain in the back and disturbance of the respiratory rhythm are not often present in phthisis. Hysteria, uterine, or spinal disorder may be eliminated by careful examination. Finally, the beneficial results of treatment may be appealed to to sustain the theory of the etiology of the cases.

LESIONS OF PERIPHERAL NERVE-TRUNKS.—In the July number of the *American Journal of the Medical Sciences*, Dr. Weir Mitchell publishes an interesting paper on nerve-lesions, illustrated by five recent cases, which he has very carefully noted and studied. Nothing which we know as yet explains all the clinical phenomena of these interesting cases, and, in all probability, some of the variations in the symptoms observed are to be attributed to differences in the character of the disorder affecting the nerve-trunks, or even to the nature of the causes originating the active pathological condition. In one of the cases, among the various points of interest none exceeds in value the abrupt extension of the areas of lessened sensation which was seen after section of the median and radial nerves. This was not to be accounted for upon any knowledge which we now have of the peripheral distribution of nerves, since in one case the dysæsthesia spread far beyond the region tributary to the nerve stretched or cut; and, in the other, in some directions did not cover the whole regions usually affected after radial nerve-sections. Generally speaking, the symptom is to be considered as one of the many forms of shock. A sudden injury to a nerve already morbidly altered gives rise to an inhibition of function in certain closely related centres. The disturbance might be in the direction of motor or of sensory inhibition, and both forms are among the rarer phenomena of nerve-wounds from rifle-balls. The fact itself is less surprising than its permanence, nor is it easy to comprehend the precise nature of an influence which may act on such varied functions, and act so persistently. In a case of section of the infra-orbital nerve for facial neuralgia, the remarkable feature was the fall of temperature, a symptom exceptionally rare in any form of neuritis, whether of internal or traumatic origin.

EARLY CEREBRAL SYMPTOMS OF TUBERCULOSIS IN THE ADULT.—Dr. Daremburg relates at some length in the *Archives Générales de Médecine* for June, 1883, the histories of four cases of tuberculosis in which the actual onset of the disease was preceded for several years by a very noticeable change in disposition. The patients, who were of a lively and amiable disposition, attentive to their friends and families, and interested in all that was going on about them, became morose and sullen, neglected their business and displayed an unwonted irritability and peevishness. No cause could be discovered to account for this change of character. In the course of a few years the symptoms of tuberculosis manifested themselves, and the patients eventually all died of tubercular brain affections. From a study of these cases the author concludes: That when in an adult there is observed a marked change in character, consisting especially in a general apathy and a notable indisposition for study or work, for which no cause can be determined, there is reason to suspect the possibility in the future of the development of tuberculosis. The prognosis is yet more grave if there be an hereditary predisposition to this disease. And further, when once the existence of tuberculosis becomes established a fatal termination from tubercular meningitis may be looked for.

PASSAGE OF A LUMBRICOID WORM THROUGH THE EAR.—Dr. Paul Dagand writes to the *Journal de Médecine et de Chirurgie Pratique* for June, 1883, concerning an epidemic of measles occurring during the first quarter of the present year. In every case he observed a peculiar complication in the presence of a large number of lumbricoids, which were discharged from both the mouth and the rectum, sometimes to the number of fifty or more. He was called in haste, one day, to see a child suffering from measles and secondary pneumonia, from whose ear the father said a worm was coming. The child had complained for two days of violent earache, and Dr. Dagand, upon his arrival, discovered a piece of a worm, about a line in diameter, in the external auditory canal. A piece about two inches in length had

already been torn away, and the attempt to remove the rest was successful. The entire length of the lumbricoid was about five inches. The worm had apparently passed up through the Eustachian tube and perforated the drum. There was an otorrhœa for some days, which gradually disappeared. When seen two weeks later the child was well with but slight impairment of hearing.

RHEUMATISMAL CONJUNCTIVITIS.—Dr. Maurice Perin, in a previous communication to the Academy of Medicine of Paris, related a number of facts tending to prove the existence of a form of conjunctivitis due to rheumatism. This resembles, especially in the rapidity of its development and the gravity of its symptoms, gonorrhœal ophthalmia. He has now collected (*Journal de Médecine et de Chirurgie Pratique*, June, 1883) a number of cases of different observers, which would seem to establish without doubt the existence of this variety of conjunctivitis, in which the integrity of the cornea is seriously endangered in spite of the most skilful treatment. This affection is sure to be confounded with gonorrhœal ophthalmia whenever there is any urethral discharge, even though the latter is not specific. The rheumatismal conjunctivitis is not always purulent, and may, in a less degree and without changing its nature, affect the form of simple catarrhal conjunctivitis. To the treatment by nitrate of silver in mitigated stick or in solution, it is well to add frequent lotions or spraying of the eye with alcohol and water of the strength of one part to four.

EXPERIMENTAL KERATITIS AND STRICKER'S THEORY OF INFLAMMATION.—Dr. J. L. Minor, of New York, in a brief paper in the July issue of the *American Journal of the Medical Sciences*, claims the establishment of the immigration theory; because the pus-cells are similar in appearance to the white blood-corpuscles; they can be traced from the corneal periphery to the point of irritation; and having also gained access to the corneal tissue through the eschar, they are most abundant immediately around this centre, where we can still recognize dead, but intact, corneal corpuscles. The corneal corpuscles show signs of proliferation some time after the cell immigration has set in. And this proliferation gives rise, not to pus-cells, but to new corneal corpuscles, and they are strictly limited to the zone surrounding the dead corneal corpuscles; whereas leucocytes, or pus-cells, in abundance, can be found in various parts of the cornea, at a distance from this point.

ALIMENTATION OF INFANTS AFFECTED WITH THRUSH.—When new-born children, affected with thrush, refuse to take the breast or the bottle, Dr. Wiederhofer (*Journal de Médecine de Bordeaux*, June 10, 1883) advises the pouring of milk by means of a funnel through the nasal fossæ. This mode of alimentation is not difficult. When the milk enters the pharynx it provokes reflex movements of deglutition and is propelled into the stomach. The author has been enabled by this means to nourish infants for three and four weeks in succession. The same procedure is useful in children born before term, in whom there are no spontaneous movements of deglutition.

SALT WATER EXCURSIONS IN THE TREATMENT OF ASTHMA.—Professor Münter, upon the strength of his personal experience, recommends a daily excursion of three or four hours' duration upon the water as affording a remedy of the greatest value in certain cases of asthma. He regards it as very useful also in anæmia, and remarks upon the longevity and excellent health of seafaring people as confirmatory of his experience.—*St. Petersburger Med. Wochenschr.*, June 9, 1883.

A DAILY EDITION of the *Peoria Medical Monthly* was published by its enterprising editor during the session of the Illinois State Medical Society.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 4, 1883.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION AND OUR CABLED REPORT.

IN the present issue we have the pleasure of presenting by cable despatch the report of the meeting of the British Medical Association, held in Liverpool, England, during the past week. In connection with this report we are also enabled to publish in full the admirable address on surgery, delivered before the Association on Wednesday, by Mr. Reginald Harrison, of Liverpool. We take a special pride in so doing, as we are thus enabled to bring within the reach of our readers, in the shortest possible time, the doings of an Association in which the American profession is very much interested.

To such as read the report, and the able address to which reference has already been made, we believe it will be quite apparent that the end justifies the means. At least, our readers are enabled to secure very much in advance of the arrival of the English journals the publication of the proceedings of this model Medical Association, and learn with the least possible delay what business it transacted during the past few days.

It may not be unpardonable, in connection with the cabled report itself, to allude with satisfaction to some of the possibilities of medical journalism in this country. We have demonstrated, we believe, the fact that a scientific medical meeting in Great Britain can be accurately reported and published in New York within a few hours after the final adjournment has been announced. This too, we are assured, is the first time in the annals of telegraphy that the report of a medical meeting has been cabled. But ordinary telegraphing of medical meetings is now so common, and even daily editions of medical journals so frequent, that we have a becoming pride in believing that our readers are prepared for any novelty which may combine enterprise with utility.

As will be seen, the meeting was largely attended and considerable interest was manifested in its proceedings. The addresses before the general sessions, as well as those before the sections, were duly appreciated as creditable productions. Mr. Harrison's address speaks for itself. The address of Dr. Creighton on Pathology, as a candid exposition of the present status of a special department of our science, was fully representative as to learning of author and scope of subject. But we shall have

an opportunity of presenting this address in full in a future issue.

Of course many topics, having more or less reference to the government of the Association, were discussed in the meetings of the Council and general session, but those having reference to state medicine and professional relations will be of more or less interest to the medical men on this side of the Atlantic. Ethical questions bother our English cousins as they do ourselves. The same problems regarding proper ethical associations present themselves there as here, and the same indefiniteness of conclusion and hesitancy of positive and decided action manifest themselves. But these questions always gain in importance by discussion, and the general medical mind is gradually becoming prepared for the adoption of broad, liberal, and consistent principles.

The reports of the Sections, which will be presented in full to our readers in due time, will show how much of useful work was done during the afternoon sessions, not only in the number and value of papers presented, but in the earnest and instructive discussions which they called forth. The importance of some of these is foreshadowed in our cable despatches. How different indeed from similar exhibits in the sections of the American Medical Association.

The Meeting of the British Medical Association, to use the words of our correspondent, "was admitted to be one of the most successful yet held." This could hardly have been otherwise, considering the extensive preparations made to that end, the admirable organization of the Association, and its extensive working capabilities. It is safe to say that no medical or scientific body equals it in these respects. There are peculiar facilities offered to such an end which do not exist elsewhere than in Great Britain. Take, for instance, the American Medical Association as the corresponding medical organization in this country. By comparison with that in Great Britain it suffers in every way. In the latter country the profession is compactly associated in a comparatively limited area. Its main interest centres in London. There are its leading medical journals and its leading medical influences. This medical centre is within easy range of every part of the kingdom. The attendance of the best men can always be secured without much sacrifice of individual time, and with comparatively small personal inconvenience. In this country the National Association has a membership necessarily widely scattered, has, so to speak, an ever-changing and floating constituency, and there is little, if any, stability to its organization. But this is more by way of hoping for what may be than what is.

Socially our English brethren, on occasions like the present, generally manage to make the most of surroundings. There is one feature in their entertainments, they are not peculiarly burdensome to the local organizations, as extra expenses are divided among individual members. This is also a matter worthy of more extended imitation among those of our medical brethren so given to entertain and to be entertained. There does not seem to be any lack of enjoyment on these occasions, nor of sumptuousness in the character of the banquets, due to the fact that each individual is willing to discharge his own indebtedness. The gathering at

the soirée on Wednesday evening was unusually large, numbering fully three thousand guests, and including a large proportion of ladies.

It is gratifying to note the national interchange of courtesies at the annual banquet on Thursday evening. The honored president of the American Medical Association, Dr. Flint, worthily represented his countrymen in his admirable toast to the British Medical Association, while Mr. Ernest Hart paid, in eloquent terms, a fitting tribute to the distinguished guests who graced the occasion. Nothing could be in better keeping with the spirit of fraternal professional feeling existing between the two countries, nor better represent the cordial reciprocity of good will and generous emulation in the higher professional pursuits. Each year the opposite shores are being brought nearer together, and even now we feel pulse-throbs along the wire.

CONTAGION AND QUARANTINE.

THE situation in regard to the yellow fever is considered quite satisfactory, notwithstanding the fact that the disease is "knocking at the door" of many of the Northern as well as Southern ports. The action taken by the New Orleans authorities in requesting the Governor to order all infected vessels out of the Mississippi River, and to allow no more such vessels to enter its mouth or come up to the quarantine station, is regarded as one of the most important events that has occurred in connection with the efforts of the Government in preventing the yellow fever's introduction into that port. Governor McEnery at once telegraphed to the Surgeon-General of the Marine Hospital Service to ascertain whether vessels turned out of the Mississippi quarantine would be received at the Ship Island Refuge Station, and was promptly informed that all infected vessels would be received there. This action at once obviates all necessity for the continuance of the inspection service of the "Sanitary Council of the Mississippi Valley" at Memphis, Vicksburg, etc., which has created some dissatisfaction amongst steamboat lines assessed by the "Sanitary Council" to keep up the inspection.

Medical officers have been stationed at London and Liverpool, England, for the purpose of informing the Government as to the condition of said ports, and to make sanitary inspections of all vessels sailing to United States ports, notifying the Government by cable whenever an infected or suspicious vessel departs for the United States. Dr. Robert Mainegra, of New Orleans, has been appointed Sanitary Inspector for the port of Vera Cruz, Mexico, and is now on his way to that place to perform similar duty. Pending his arrival, the consul at Vera Cruz has been requested to cable the departure of all vessels from that port. Dr. Burgess has been on duty at Havana as Sanitary Inspector since July 1st. The consuls at other ports where infectious diseases prevail, as well as those mentioned above, have been directed by the Secretary of State, at the request of the Secretary of the Treasury, to inform all out-going ships to put in at Ship Island, or Sapelo Refuge Station, before proceeding to their port of destination, for the purpose of being inspected, thereby saving detention, as

they will be ordered there by the municipal authorities if they attempt to enter any Southern port.

The Secretary of the Treasury decided a few days ago that the quarantine law of April 29, 1878, is again in force, the law repealing it having been a temporary law, which expired by limitation on June 2d last. This decision is of the utmost importance, as it relieves the apprehension that has been felt regarding the powers of the Government in controlling quarantine. The law as it now stands, with the power given at the last session of Congress "to maintain quarantine [stations] at points of danger," gives us the best and most powerful quarantine law we have ever had. Acting under this decision, the Secretary directed the Collector of Customs at Boston to enforce the law and regulations against the British steamer *Bavarian* with a cargo of Egyptian rags, which was expected to arrive at that port. The regulations referred to are as follows:

"Until further orders, no vessel from any port of the Black Sea, or the Sea of Azof, conveying any rags, furs, skins, hair, feathers, boxed or baled clothing or bedding, or any similar articles liable to convey infection, nor any vessel from any port of the Mediterranean or Red Seas having on board such articles coming from Southern Russia, shall enter any port of the United States until such articles shall have been removed from the vessel to open lighters, or to some isolated locality, and the vessel disinfected and thoroughly ventilated; and the suspected articles shall be disinfected, either by chemical agents and exposure to free currents of air, or by burning, as shall be determined in each case by the Surgeon-General of the Marine Hospital service.

"The certificate of the State or municipal quarantine officer of health may be accepted as satisfactory evidence of compliance with these regulations on the part of the vessel."

A sanitary conference was held at Fortress Monroe on July 28th, to consider the question of establishing a national quarantine station near the Capes; there were present Surgeon-General Hamilton, U. S. Marine Hospital Service; Dr. Smith Townsend, President of the Washington Board of Health; Dr. George H. Benson, Health Commissioner of Baltimore; Dr. J. G. Cabell, President of the Board of Health of Richmond; the Health Officer of Norfolk and Newport News; Hon. H. Libby, Member of Congress; Colonel Loder, Commander Fort Monroe; Captain Evans, U.S.N., Lighthouse Inspector; General Grover, Member Norfolk City Council; the Mayors of Newport News, Portsmouth, and Norfolk, and many other prominent men of the various towns in the vicinity. After a full discussion of the subject it was decided to establish a National Quarantine Station at Fisherman's Island, some twenty miles from Norfolk, near Cape Charles; and pilots were instructed to take all vessels from foreign ports there for inspection. By the establishment of this station all cities on the Chesapeake are protected from the approach of infected vessels. Heretofore Baltimore has permitted such vessels to come up to her quarantine station and take care of them there, but the fear of panic has decided the Health Commissioner to join in urging a national quarantine station between the Capes where all infected vessels can be cared for without endanger

ing Baltimore. The Revenue vessels and hospital steamer John M. Woodworth will also be on guard at the Capes to prevent vessels passing up the bay until inspected.

A NEW THEORY OF THE NATURE OF BRIGHT'S DISEASE.

PROFESSOR SEMNOLA, of Naples, has for some years been studying the subject of Bright's disease with the view of demonstrating the humoralistic origin of the disease. At the International Congress in London, two years ago, he propounded the view that nephritis is consecutive to an albuminous dyscrasia—a view which Gubler had already suggested before him. Semnola's theory was received with respect, but gained no adherents. Recently this industrious student came all the way to Paris and laid before the Académie de Médecine the results of his further investigations. In brief, he has injected or transfused into the blood of various animals different kinds of albumen, and he finds that the effect is first to produce albuminuria, then nephritis, the results varying with the kind of albumen. He also states that in Bright's disease there is a general transudation of albumen, this substance being found in the bile (where it does not exist in health), in saliva, and various other secretions and fluids. The cause of renal albuminuria, therefore, is to be looked for in the blood. Here the normal serum-albumen, which does not easily transude, becomes changed and passes into the urine. In so doing it sets up the different inflammatory and degenerative processes which characterize the kidneys in Bright's disease. Professor Semnola found in his experiments that the form of albumen which is most apt to transude and cause irritative trouble is the ordinary egg-albumen. This stands at one end of the list, serum-albumen at the other.

Professor Semnola's exposition of his views was received with great applause by the Parisian academicians. No discussion, however, followed. It was not stated whether there were any practical deductions to be made from this dyscrasic hypothesis. The inference is, however, that egg-albumen should be forbidden and serum-albumen prescribed as an article of diet.

LUPUS AND TUBERCULOSIS.

DR. J. DOUTRELEPONT, of Bonn, has examined seven cases of lupus with the view of determining the presence of the bacilli tuberculosis. In the diseased tissue of all of these cases the organisms were found, though in varying amount. The investigator concludes, therefore, upon this and certain clinical grounds, that lupus is a tuberculosis.

Dr. Demme has also investigated this subject and has found the tubercle bacilli in the nodules of lupus nodosus and in lupus serpiginosus. He also argues therefrom the identity of the two diseases. On the other hand, a writer, presumably Spina, in the *Wiener Medizinische Zeitung*, takes an entirely different view and asserts that the presence of these bacilli simply shows that they are not pathognomonic of tuberculosis, or that, though different bacilli, they take the same staining. The writer in question arrays all the clinical and pathological evidence possible against the view of the identity of the two diseases.

HOW TO SLEEP ON A RAILROAD TRAIN.

MANY weary persons have tried to solve this problem, and have tossed about for hours in restless disappointment.

Dr. Outten, a German physician, has applied the laws of physiology to the matter and announces (*Allg. Central-Zeitung*) a satisfactory solution of it all. If a person lies down with his feet toward the engine, the movement of the train tends to draw the blood from the brain to the feet, cerebral anemia is produced, then sleep. If, on the other hand, the person lies with his head nearer the locomotive (as is the custom in Germany), the movement of the train produces a cerebral hyperemia incompatible with sweet repose. Dr. Outten has verified his view with many experiments.

Dr. O.'s directions are hardly needed in America, where the berths of sleeping-cars are generally made up so that the position is as indicated by physiology and our German *confrère*. In this connection, however, we would say that many persons are unaware of the fact that additional comfort and better sleep in travelling can often be obtained by judiciously using the bromides.

THE YELLOW FEVER AND ITS CONTROVERSIES.

THERE has for some time been much lack of harmony among the sanitarians of the Mississippi Valley. The discord has been intensified since the National Board of Health gave up control of quarantine. The Sanitary Council of the Mississippi Valley, the Louisiana State Board of Health, the United States Marine Hospital Service, and the New Orleans City Board of Health have been the active participators in the sanitary dissensions. The quarrel, though unfortunate, has perhaps had one good result: it has forced the authorities to be extremely alert against the yellow fever, lest the reproach of allowing that disease to get into our ports be made against them.

It appears, however, that matters have become a little too personal and acrimonious. On July 20th Governor McEnery, of Louisiana, issued the following proclamation:

"In accordance with the preamble and resolution of the Louisiana State Board of Health, adopted July 12, 1883, a copy of which is hereto annexed, and in consideration of the imminent danger that the city of New Orleans, the State of Louisiana, and the Mississippi Valley are now in from the arrival at quarantine of infected vessels, any unnecessary intercourse between the Mississippi quarantine station and other quarantine stations and the city of New Orleans is hereby strictly prohibited, and any permission for that purpose heretofore granted is hereby revoked. The laws of Louisiana and the rules and regulations of the Board of Health must be rigidly enforced and obeyed in this and all respects while danger continues. Intercourse between the quarantine stations and New Orleans must be under the exclusive control of the Board of Health. I invoke the vigilance and co-operation of all good citizens during this season of threatened calamity. This order will be communicated by the Board of Health to all persons concerned therein."

Shortly after this, the Louisiana State Board of Health held a meeting and unanimously passed the following resolutions:

Whereas, Dr. J. H. Rauch, the Secretary of the Board of Health of the State of Illinois, has recently visited New Orleans and directly interfered and tampered with the health operations of the State Board of Health of Louisiana; and

Whereas, Since the dissolution of the National Board of Health there has been an effort made by illegal bodies to assume to perform its pernicious functions and mischievous tendencies; be it

Resolved, That the President of this Board be and he is hereby requested to respectfully suggest to his Excellency the Governor of Louisiana to confer with his Excellency the Governor of Illinois on the propriety of confining Dr. J. H. Rauch to health operations within his own State, and to instruct him to cease his designing efforts to impair public confidence in the State Board of Health of Louisiana.

This is a rather severe snub to the energetic Illinois official; it at least does the injustice of not saying that he is Secretary of the Sanitary Council of the Mississippi Valley; and evinces, we fear, the need of some moral sanitation in the great Southwest.

This Sanitary Council has undertaken to continue part of the work of the National Board of Health, acting in antagonism to the Marine Hospital Service. It has, however, been beaten in the various measures it has adopted, and has had to give up its steam-launch.

News of the Week.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.—The first two numbers of this Weekly have come to hand. While fully appreciating the difficulties under which the editor, Dr. N. S. Davis, has labored in starting a new medical journal, we confess to some disappointment at the result. The first number contains the address of the President of the Association, which has been published in full by several journals, lay and medical, two months ago. This should have debarred it, according to the rules which governed the publication of the Transactions, from appearance in the official journal, and would appear to establish the precedent that those papers which, in violation of the rules, have already been published elsewhere, will ultimately find a place in the official Transactions. Both numbers are largely made up of the doings of the Association. There are also departments for progress of medical science, news, reviews, correspondence and editorials. We bespeak for this enterprising periodical all the success which it may deserve, and welcome the veteran Editor to the higher walks of medical journalism.

AMERICAN DERMATOLOGICAL ASSOCIATION.—The next annual meeting will be held at Lake George, August 29, 30, and 31, 1883. Dr. R. W. Taylor, of New York, President, and Dr. Arthur Van Harlingen, of Philadelphia, Secretary.

DR. H. N. HEINEMAN, of this city, has been elected Professor of the Principles and Practice of Medicine at the Woman's Medical College of the New York Infirmary.

MOUNT SINAI HOSPITAL.—Professors A. L. Loomis and A. Jacobi have resigned as visiting physicians to this institution, and have been made consulting.

THE INDIANA STATE BOARD OF HEALTH is a failure, according to the *Fort Wayne Journal of Medical Sciences*. The provisions of the law are not so much for the benefit of the public health as of the politicians. Board of Health failures are becoming unpleasantly numerous.

PASTEUR OFF FOR EGYPT.—M. Pasteur having offered to organize a mission for investigating the cholera in Egypt, the Hygiene Commission has endorsed the scheme. The mission will consist of M. Roux and M. Thuillier, of M. Pasteur's laboratory, M. Strauss of the Faculty of Medicine, and M. Nolaco. M. Pasteur has written to Lord Granville to solicit the grant of facilities to the mission in Egypt.

THE OPHTHALMOLOGICAL SOCIETY OF GREAT BRITAIN held its third annual meeting on July 6th, electing Mr. Jonathan Hutchinson President.

THE CHOLERA continues to be confined to Egypt, being particularly severe at Cairo. Between three hundred and four hundred deaths are reported daily. It is believed that many more deaths from cholera occur in Alexandria than are reported. The English, who reject quarantine as interfering needlessly with commerce, have undertaken their system of inspecting incoming vessels and disinfecting those having disease on board. It is reported that cholera exists in Rio Janeiro. Precautions against the importation of Egyptian rags are being taken by the authorities in American ports.

THE LOUISVILLE MEDICAL NEWS.—Dr. L. S. McMurtry has retired from the *News*, and is succeeded by Dr. H. A. Cottell, formerly one of its editors.

DR. FRANCIS DELAFIELD has been elected full Professor of Principles and Practice of Medicine, College of Physicians and Surgeons, New York.

A SANITARY CONVENTION.—Our Western brethren revel in sanitary conventions. One is to be held at Muskegon, Michigan, under the auspices of the State Board of Health, on Thursday and Friday, August 23 and 24, 1883. The objects are the presentation of facts, the comparison of views, and the discussion of methods relating to the prevention of sickness.

THE DEATH OF DR. GEO. H. FISHER.—Dr. Fisher, son of Dr. George J. Fisher, of Sing Sing, N. Y., died suddenly, July 23d, at Baltimore, Md., aged twenty-nine years. After receiving his preparatory education at the military schools of Dr. Holbrook and the Mt. Pleasant Academy, he was graduated at the Medical Department of Columbia College in 1878. Dr. Fisher practised his profession for some time in connection with his father, and afterward at Round Hill, Conn. On the 22d of February last he was married to Miss Florence Jobbins, of Brooklyn, and in the following April went to Baltimore, Md., in the interest of a New York mercantile house. He remained in Baltimore until the time of his death. Dr. Fisher retired to his room in usual good health on the evening of July 23d, and at an early hour of the morning was found dead in his bed, his spirit having passed away apparently without a struggle. The profession will deeply sympathize with the distinguished father of the deceased in his deep affliction.

THE LONDON HOSPITAL SCHOOL.—Mr. Jonathan Hutchinson has resigned his position as senior surgeon, and has been appointed Emeritus Professor of Surgery. Dr. Tidy has resigned his position as Lecturer on Chemistry.

THE UNIVERSITY OF COLORADO announces the opening of a Medical Department at Denver, with preliminary examinations and a four-years' graded course. We trust that the effort at higher medical education is a sincere one and will prove successful.

ETHICS IN VERMONT.—A member of the Vermont State Medical Society is shown by a correspondent of the *New York Medical Journal*, to have advertised a "sure cure" in a local paper. The State Society in its ardor to keep out New York delegates, forgot to look at home.

POLITICS AT THE GERMAN HYGIENIC EXHIBITION.—The German correspondent of the *Medical Press and Circular* gives the following account of some of the true inwardness of the German Hygienic Exhibition. Speaking of the Presidents of Sections in the Exhibitions, and of the fitness of the appointment of Professor Guret, of Berlin, as President of the Section of Field Hygiene, the special correspondent of the *Allgemeine Wiener Med. Zeitung* goes on to say that, if the choice in this case was in every way suitable, it has aroused a decidedly disagreeable feeling of surprise in medical circles to observe that the choice of Presidents of Sections has fallen upon some not in the first rank, whilst a Virchow and an August Hirsch have only received appointments as *members* of the Sectional Committees. The reason why Virchow, the first hygienist—a man to whom the city of Berlin is so much indebted, and of whom it is proud—was not placed at the head of the committee (in case he had not the choice of being so, and declined it) can only be found in political causes. "But what grounds have caused the setting aside of Professor Geh. Med. Rath. August Hirsch? August Hirsch is esteemed in professional circles as one of the first epidemiologists, and outside the scientific world he has been only once spoken of. That was when he returned from Russia, three years ago, from a journey of investigation into the plague at that time rife in that country—a journey undertaken at the instance of the Imperial Government. He had sent in his report to the proper authorities, the Imperial Health Office, and awaited their decision. As this was too long in coming, and as the Health Office made no sign of noticing his work, he withdrew it and published it at his own expense. This procedure later on cost Director Struck a very uncomfortable quarter of an hour in the Reichstag, and therefore it may well be said that since that time Herr Hirsch has not been a *persona grata* in the higher regions. Such reminiscences cannot be often enough freshened up. They afford in the present case, and in still higher degree for our own *epigonen*, a small but valuable measuring-staff, which will aid us in forming a judgment of persons and of the movements of the times."

SUPPOSED SUICIDE OF A YOUNG PHYSICIAN.—A very sad event was the sudden death last Sunday of Dr. Milligan Patchin, of this city. While engaged in cleaning and examining a pistol it went off, with a fatal result.

British Medical Association.

FIFTY-FIRST ANNUAL MEETING.

Held in Liverpool, Tuesday, Wednesday, Thursday, and Friday, July 31, August 1, 2, and 3, 1883.

(BY DIRECT CABLE TO THE MEDICAL RECORD.)

TUESDAY, JULY 31ST—FIRST DAY—MORNING SESSION.

THE opening exercises of the Association consisted of Church service at 10.30 A.M., held at the Pro-Cathedral. A sermon was preached by the bishop of Liverpool. The cathedral was crowded. The music was inspiring. The responses were those of heartfelt welcome. The sermon was eloquent, and the venerable and scholarly clergyman dwelt at length on the intimate relation existing between the physician and his patient, the moral obligation of the former to the latter, the dignity and paramount importance attached by the Christian religion to the human body, and the zeal and devotion thus called forth for untiring efforts in behalf of its healthful preservation.

One thousand members were present, together with a large number of Americans and other foreigners.

FIRST DAY—AFTERNOON SESSION.

The first general meeting of the Association was held in the College, Shaw Street, at 3 P.M. WILLIAM STRANGE, M.D., Senior Physician to the General Infirmary, Worcester, President, in the Chair.

DR. C. G. WHEELHOUSE, of Leeds, Chairman, presented the

REPORT OF THE COUNCIL,

in which important topics requiring the action of the Association were set forth. Among the items of business liable to give rise to much stormy discussion were The Medical Act Amendment Bill, which involved eligibility to registration in the Medical Register as a medical practitioner, unless, in addition to the licence of the General Medical Council, he shall be attached subsequently to one of the universities or medical corporations, and be authorized to register the title so acquired.

The Parliamentary Bills Committee of the Association had proposed the above qualification, to which some of the branches of the Association had already manifested a vigorous opposition, and were prepared to argue against the restrictions involved in the propositions.

The Homœopathic question startled our brethren here as manifestly as it did those of the American Medical Association; but when the book was opened, the same knotty problems were found on page after page, and they seemed no nearer solution than in our own country, especially when it was learned that they had a close relationship to lawyers and the High Chamberlain.

The Bill requiring

NOTIFICATION OF INFECTIOUS DISEASES

will create as much dissension here as did the question of the abuse of medical charity in New York, and there was no well-grounded prospect that the question

was any nearer a satisfactory answer in one case than it was in the other. The law requires every medical practitioner attending on, or called in to visit any person suffering from any infectious disease, to forthwith fill up, sign, and deliver or send to the medical officer at his office a certificate or declaration stating, etc. In one instance, at least, the Town Council appointed as their medical officer of health a *homœopath*, and the significant question had been asked, Was it likely that such a man could expect active support from the medical profession, or that they would report their cases to a man who was a *homœopath*? The energies and anxieties of the medical profession throughout the United Kingdom are likely to be taxed to their utmost for a satisfactory answer.

FIRST DAY—EVENING SESSION.

The Association met at 8 P.M. The meeting was largely attended and the audience listened attentively to

THE ADDRESS OF THE PRESIDENT-ELECT,

A. T. H. WATERS, M.D., F.R.C.P., of Liverpool.

The President of the Association, next delivered his address, confining himself to a review of the progress and prospects of medical science. During the past few years no science had made greater strides, or had more largely increased its following in earnest and determined workers. As a striking evidence of this was the continued prosperity of the Association, its increase in membership, and its extension of influence. Not only was the spirit of progress manifested in every department of original research, but it had infused itself in the work of the general practitioner, who was eager to receive and adopt advanced views and improved practices. He also sketched somewhat in detail the various advancements that had been made in the different departments of medicine, not only in Great Britain but throughout the civilized world, and argued that the prospects of the future were never more promising, with a field constantly enlarging, and with continued increase of earnest and determined workers.

After the adoption of a resolution of thanks, formally seconded, to the President for his address, and the trans-action of some miscellaneous business, the Association adjourned to meet at 11 A.M., August 1st.

WEDNESDAY, AUGUST 1ST—SECOND DAY.

The second general meeting of the Association was called to order at 11 A.M. by the President, PROF. WATERS, of Liverpool.

The special order was the

ADDRESS IN SURGERY,

which was delivered by REGINALD HARRISON, F.R.C.S., Surgeon to the Royal Infirmary, Liverpool.

(For the address in full, see page 113 of this number of THE RECORD.)

The speaker was listened to with profound attention by a large audience, and at the close received a hearty applause, followed by a resolution of thanks, with a second, expressing a high appreciation of the ability and character of his discourse.

It was then arranged to hold

THE NEXT ANNUAL MEETING

at Belfast, Ireland, under the presidency of James Cum-
ing, M.D., F.K.Q.C.P., Prof. of Theory and Practice of
Medicine, Queens College, Belfast.

This was in accord with an invitation received from the profession of Belfast at the semi-centennial meeting held in Worcester, England, last year.

WORK IN SECTIONS.

Among the papers and discussions before the Sections noteworthy mention is made of the following:

Section in Public Medicine.—T. Pridgin Teale, M.D., F.R.C.S., of Leeds, President. Paper "On the Injury Done to the Health of the Young by the Present System of Education," by Martin Johnson, Esq.

A communication on "The Sanitary Condition of Liverpool" gave rise to a stirring discussion, and was especially interesting at the present time, in view of some apprehensions which have been manifested since the outbreak of cholera in Egypt. The authorities and the profession were on the alert, and it seemed very improbable that the disease would succeed in making an ingress into that port.

Section in Ophthalmology.—T. Shadford Walker, M.R.C.S., of Liverpool, President. Discussion on tests for color-blindness, opened by Dr. W. A. Brailey, of London, who was followed by Dr. Snellen, of Utrecht. The subject was discussed with special reference to the acuity of vision and color-sense in students and sailors.

Section in Psychology.—T. L. Rogers, M.D., of Rainhill, President. Discussion on the employment of the insane, opened by Dr. D. Yellowless, of Glasgow, First Vice-President of the Section. The general tone of the discussion was in favor of discriminate employment of this class of unfortunates.

SOIRÉE IN THE EVENING.

The President and Local Committee gave a *soirée* in the Art Gallery, at which three thousand guests were present. The affair was entirely successful.

THURSDAY, AUGUST 2D—THIRD DAY.

The third general meeting was called to order at 10 A.M. by the President, Professor Waters, and was devoted entirely to business matters pertaining to the Association.

WORK IN SECTIONS.

The day was spent chiefly in work in the various Sections which were largely attended and noteworthy papers were read and subjects discussed as follows:

Section in Diseases of Children.—SAMUEL JONES GEE, M.D., F.R.C.P., of London, President, delivered an address which consisted in a historical sketch of the literature of children's diseases. Beginning with the ancients he referred especially to Hippocrates' description of *mumps*, and next spoke of Rhazes as the author of the first treatise on the subject of diseases of children. No addition was made to our knowledge until the appearance of Glisson's book on *ricketts* in the seventeenth century. The speaker also alluded to Lydenhain's description of

measles, scarlet fever, whooping-cough, and St. Vitus' dance. In the last century, croup, acute hydrocephalus, and the eruptive fevers were especially referred to, and in the present century the study of morbid anatomy and the methods of physical examination of the living subject.

Section in Public Medicine.—DR. NORMAN KERR, of London, read a paper on "The Present Position of the Habitual Drunkards Movement."

DR. C. R. DRYSDALE, of London, read a paper on "The Mortality of the Rich and the Poor," in which he compared the mortality of total abstainers with that of moderate drinkers.

DR. FRANCIS IMLACH, of Liverpool, read a paper on "Quarantine," and DR. STOCKER, late Government Emigration Inspector at Queenstown, on "The Sanitary Condition of the Mercantile Marine." The author of the last paper made special reference to the inspection of ships in America as being very complete, and also referred to the import of rags as a probable means of conveying infection.

CAPTAIN DOUGLAS GALTON, C.B., F.R.S., read a paper on "Hospital Construction." The author reviewed the subject thoroughly and maintained that hospital buildings should be of the simplest kind; that they should not be built on the supposition that they can remain as enduring structures, and for the reason that they are very liable to become dangerously infected.

A portion of the day was set aside for visiting

PLACES OF INTEREST

including the docks, some of the large steamships, art galleries, public halls, hospitals, and public libraries.

BANQUET IN THE PHILHARMONIC HALL.

In the evening a public dinner was given at Philharmonic Hall.

Over four hundred members were in attendance, and numerous guests. Dr. Austin Flint, of New York, was present, and was received with great applause when he proposed in most cordial terms and in behalf of the American Medical Association the toast: "To the British Medical Association."

Mr. Ernest Hart, editor of the *British Medical Journal*, proposed with ready and expressive words the toast, "To our Visitors," which was responded to by Dr. Fenwick, of Montreal, who hoped that on some future occasion the British Medical Association would hold a meeting in Canada, where it would meet with a hearty reception.

FRIDAY, AUGUST 3D—FOURTH DAY.

The Association met in general meeting, at 10 A.M., and was called to order by the President. After the transaction of some routine business the

ADDRESS ON PATHOLOGY

was delivered by C. CREIGHTON, M.D., formerly Demonstrator of Anatomy, Cambridge University. The speaker showed how diseases such as cancer and tubercle acquired an autonomy and assumed an individual existence in the bodies of those in whom they took origin and subsequently infected. The address was listened to with marked attention by a large and appreciative audience throughout its entire delivery.

The author received a cordial vote of thanks for his address.

The concluding general meeting was held at 2 P.M., when hearty votes of thanks were accorded to the local officers, with an interchange of congratulations, and thus terminated most successfully the fifty-first annual meeting.

In the evening the Mayor of Liverpool gave a *soirée* at the Town Hall, where were entertained a brilliant gathering of ladies and gentlemen made up of members and guests.

Arrangements were perfected for numerous excursions to places of interest near Liverpool, to take place on Saturday, August 4th, for the members and their friends.

Reviews and Notices.

DIE ANÆMIE. VON S. LAACHE. Universitäts-Programm für das 2 Semester, 1883. Christiania: Die Malling-sche Buchdruckerei. 1883.

THE very elaborate monograph before us presents the results of a long series of investigations by Dr. S. Laache, made under the direction of Professor J. Worm Müller, of Christiania. It contains so much that is new and valuable that we shall take an opportunity to discuss it fully at another time.

A TREATISE ON THERAPEUTICS: Comprising Materia Medica and Toxicology, with Especial Reference to the Application of the Physiological Action of Drugs to Clinical Medicine. By H. C. WOOD, M.D. Fifth Edition, revised and enlarged. Philadelphia: J. B. Lippincott & Co. 1883.

THE exhaustion of the fourth edition of this work in six months is a very emphatic evidence of its value and appreciation by the public. Its merits have frequently been extolled in these columns and we need add nothing now. We would suggest that the chapter on electricity should be revised by an expert; and that it would be very desirable to have something about diet-cures, climate-cures, hydrotherapy, and movement-cures in a book which is a treatise on therapeutics. We trust that the author may have an opportunity to make these additions in another six months.

ON THE RELATION OF THE CHEST MOVEMENTS TO PROGNOSIS IN LUNG DISEASE, and on the Application of Stethometry to Examinations for Life Assurance. By ARTHUR RANSOME, M.D., M.A. (Cantab.). With Illustrations. Pp. 100. London: Macmillan & Co. 1882.

THE author has devised an ingenious set of instruments by which the upward, forward, and outward movements of the chest-wall are measured and registered. With the aid of this, he has determined some interesting physiological facts, and has also, as he thinks, obtained data by which more exact diagnosis, and especially prognosis in lung disease can be given. The author is modest in his claims for stethometry, and what he does claim is supported by a large number of tabulated observations. His results are confirmed independently by Drachmann, of Copenhagen. The author has evidently expended great care and labor upon his work, which is beautifully printed.

DR. W. S. LITTLE, of Philadelphia, writes: "Please make the following correction in the report of my paper on Congenital Ectopia Lentis, read at the meeting of the American Ophthalmological Society, appearing in your journal July 28, 1883. For *divergence* please read *detachment of the retina from hemorrhage*."

Correspondence.

HOW TO PROCURE THE BEST POSSIBLE PHYSICAL CONDITION AFTER PARTURITION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of your highly esteemed journal, for June 30th, I find a rather severe and, in my opinion, unwarranted criticism on my paper entitled "How to Procure the Best Possible Physical Condition after Parturition," read before the New York Academy of Medicine, Section of Obstetrics, April 26, 1883. My critic charged me with having advised to close all wounds, suppressing all lochia, and conveys the idea that I advocate a sort of "kolpokleisis" after parturition. The doctor evidently labors under a misapprehension in regard to what I did say. I desired to call especial attention to the beneficial effects of strictly hygienic and antiseptic measures before, during, and after parturition; as they have proved in my hands, as well as in those of Tarnier, of Paris, Barnes, of London, Braun and Spaeth, of Vienna, Thomas, Lusk, Barker, Wiley, Mundé, J. E. Taylor, and many others in this city, to be the only safeguards against those manifold diseases which were formerly collectively termed "childbed fever," and claim in this city alone about *five hundred victims annually*, many of whom would live to-day, had they been attended by antiseptic and hygienic measures instead of acting under the old rule of "beware of meddling midwifery." The secretions and excretions of the parturient must also be kept in as normal condition as possible.

The touch-me-not plan having proved a rather dangerous one even among the "Indian Squaws," who cannot avail themselves of the advances in science and art, the gentle artificial dilatation of the cervix uteri during labor pain; the careful pushing back of the anterior labium oris externi uteri, the use of chloroform or chloral hydrate when indicated, the rupturing of long delaying tough membranes, the compression of the fundus uteri before and while the child is being born, the advantages of Orede's method of expressing the placenta, *but, contrary to Dr. MacGaughey's advice, without even a little tension on the cord*, is, by no means, an overrated measure—as proved by my own and that of many able accoucheurs, among whom Professor Carl von Braun, of Vienna, under whose supervision over one hundred thousand children were born, where the method had been most successfully applied. As to checking profuse post-partum hemorrhages, and to control the uterus until it had firmly contracted after parturition; the sewing up of extensive lacerations of the perineum, immediately after labor, etc.; upon these points the doctor seems to agree with me; he finds no fault with the advice to use the binder after the placenta and the secundines are born, although it has been discarded long ago in the Vienna lying-in wards; the immediate application of the child to the mother's breast as soon as she had some rest and refreshing sleep, and been made comfortable, is also approved of by my critic. But now, *mirabile dictu!* I am taken to task by the learned doctor for unnecessarily interfering with *nature* and the natural post-puerperium physiological processes, and he charges me with going too far when I remark that a little hemorrhage after parturition is a dangerous thing and should be arrested, etc.; and he lays stress upon my remark, used in a figurative sense, of course, in answer to Dr. Carpenter's question, that not a single drop of blood should appear after the completion of the third stage of labor, and that napkins removed should be perfectly free from color, etc.

In regard to this question I desire again to reiterate what I did actually say, and it was this—that Housmann's reliable experiments, in 1868, instituted upon rabbits, by injecting fluids taken from persons who died of infectious peritonitis, *inevitably caused the death* of pregnant animals; even healthy pus injected into the genitals of

animals shortly before or soon after labor, if their *vaginal* or the *mucous membranes of their uteri were wounded* or eroded, caused *always pyemia or septicæmia and death*; thus showing conclusively the great susceptibility to infections, with consequent fatal results, during the puerperal state. Especially those suffering from primary endometritis and vaginitis during pregnancy, are then usually liable to attacks of parenchymatous metritis or metrophlebitis after childbirth. Even catarrhal secretions, according to Braun, cause ulcerations of the denuded mucosa, which becomes the gate of infection and the starting point of phlegmonous inflammations of peri- and para-metritis, etc. Many cases of puerperal fever undoubtedly originate from the absorption of the foul stuff of decomposition from retained blood-clots, portions of retained placenta, the membranes, purulent matter formed in utero, and from *wounds and bruises and subsequent gangrene of the tissues of the genital tract*, where the puerpera takes the poisons of her own making, says Barnes. Now, with these facts before us, I ask is it not unjustifiable and, to say the least, ungenerous that Dr. MacGaughey says, "As for examining the genital passages of *all* puerpera after removal of secundines, and directing that all slight lacerations should be promptly closed, the advice is very good on paper, but very awkward and difficult and often very unnecessary at the bedside. Besides, the 'meddlesome midwifery' of exposing all women, and of closing slight lacerations or wounds, would involve more, much *more, danger* to the patient than letting them alone." I will, for the satisfaction of the doctor, quote the highest authority in Europe upon this point of the controversy which my critic, not I, has invited.

Braun says: "Slight lacerations of the perineum, or wounds made by episiotomy, are closely united by serres-fines or, if extensive, by metallic sutures; bruised wounds of the vagina should be pencilled with pure tincture of iodine, muriated tincture of iron, thymolized oil, or, according to Fehling, with salicylic powder (one to five of starch) applied two or three times daily. Under this treatment they usually heal in from three to five days."

Regarding the prevention of the least hemorrhage post-partum, I will quote Barnes, of London, certainly as good an authority as there is to be found anywhere. He says: "To obviate hemorrhage post-partum is to oppose septicæmia." I therefore always give, in accordance with the late lamented Prof. Elliot's advice, which I learned from him in 1866, in Bellevue Hospital Medical College, one drachm of Squibb's fluid extract of ergot (or Wyeth's), even in natural labor, after its completion, and I repeat the dose, given in sugar water, on account of the nasty taste of the stuff, until the uterus has firmly contracted, and it becomes evident that no portion of the placenta, the membranes, or of *blood, has remained in the vagina or the uterus*. The least hemorrhage from the *genitals*, again says Braun, is treated "by the application of iodine, persulphate of iron, hot-water injection, the silver wire or carbolized silk ligature." I shall continue to adduce proofs—not arguments, but undisputed facts—to convince Dr. MacGaughey that it is a good advice to close up even slightly lacerated wounds after parturition, and thus prevent bleeding and septic infection. When I speak of thus treating wounds, I do not mean to close either the uterine or vaginal canal beyond where it is injured, leaving room enough for the shedding of the degenerated lining membrane of the uterine cavity and cervical canal, which cause the lochia, and ought to be colorless and not cruenta, which means bloody. If they become so there is danger of puerperal fever, which can be avoided if all wounds are treated as stated above; nay, according to Prof. Pallen, of this city (now, I understand, of London, England), even a lacerated cervix had better be sewed up soon after parturition than to be left to nature.

Does not Prof. Pallen's advice require exposure of the parts? Does not immediate perineorrhaphy require the same? But, however, I think I have already taken up

too much of the valuable space of THE RECORD to refute the uncourteous remark of Dr. MacGaughey, when he, in a scientific criticism, uses the words "*too ridiculous, a work of supererogation*," and other not very complimentary epithets on subjects about which he seems to have a great deal to learn yet.

I am very respectfully, yours,
 RUDOLF TAUSZKY, M.D.

THE DISEASE QUESTION IN INEBRIETY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The courteous criticisms of my article on "Obscure Causes of Inebriety," by Drs. Hart and Stair, in Nos. 661 and 662 of THE RECORD, tempt me to make some suggestions.

The question cannot be solved by argument, because it is one of accurately observed facts and their meaning.

Like any other question in physical science, we must have all the facts before we can reach any clear conclusions.

We must accurately study and record the physiological and psychological symptoms, or phenomena of inebriety, and from these histories will appear the laws and forces which govern its origin and progress.

When such a study is made of a large number of cases, by many persons who are more or less competent to judge, in different parts of the country, covering a period of years, their conclusions, when unanimous on certain points, are the best authority, and are entitled to great consideration. Conclusions reached in any other way are open to question and doubt. If the asserted fact that inebriety is always a disease, cannot be sustained by clinical evidence it is an error. It is equally erroneous to deny the disease theory, unless such negations are supported by study of cases. We have repeatedly urged our critics to send clinical histories of cases, that seemed to sustain their views; or cases where the early stage was one of vice and sin, pure and unmistakable, but no one has responded so far.

For over twenty centuries inebriety has been considered a physical disease, and as a student of this phase of mental disorder we are fully conscious that the border lines of its study have hardly been touched. The wide ranges of the unknown before us are far more impressive than any present knowledge of the subject, or opinions of to-day.

If my critical friends will rise above the dogmas of to-day, and examine inebriety independent of all theory or popular notion, its magnitude will silence all doubts, and the great ocean of the unknown will stretch out before them, where each may be a discoverer, untroubled by the notions and theories of others.

Respectfully yours,
 T. D. CROTHERS, M.D.

HARTFORD, CONN.

HOW TO ABORT TYPHOID FEVER—A CRITIC CRITICISED.

[We insert the following letter in order to give *altera pars* a hearing. We must add the criticism that the writer makes only assertions, and entirely fails to prove anything whatever. A long series of carefully noted clinical observations can alone prove anything as regards the power of a remedy to shorten or modify a disease of so variable a type as typhoid fever.—Ed.]

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the *Medical Age* of June 10, 1883, is an article criticising an article in THE MEDICAL RECORD, which article was criticising the *Age* for using very strong language toward any one who said he could abort or cut short typhoid fever. The *Age* winds up its article by saying: "Dr. Davy now has the floor." Thanks for his liberality. The *Age* accuses THE RECORD of summing up the results of the recent research and debate in

France in rather a "pessimistic spirit." That old legend no doubt flitted across THE RECORD's mind when he soliloquized to himself! again the mountains labored! with minute results. The *Age* does not appear to be impressed in that way, for he says, "the debate strengthened the rational therapeutics of the disease." If the *Age* would prefix it to rational (irrational) he would be much nearer the truth; for if it was the rational system of treatment, why such pessimistic comments.

What the immortal Jenner did for small-pox has been done for typhoid fever; it has been demonstrated in over one hundred cases, and extending through five years of time, that that much dreaded disease is amenable to the proper treatment, and that an attack can be broken up and the disease cut short after passing the forming stage. Patients treated according to the hereinafter given plan, have been able to be up and about their rooms from the twelfth to the sixteenth day of medication, and some out riding on the eighteenth day. The fever leaving them, some as early as the fourth, and some as late as the eighth day, depending upon the severity of attacks and faithfulness of nurses. The above good results have been attained by the use of the following prescriptions and plan of treatment faithfully carried out:

PRESCRIPTION NO. 1.

R. Cohothedrae compound..... ̄ iv.

Sig.—Thirty drops every four hours in two tablespoonfuls of water.

PRESCRIPTION NO. 2.

R. Quinia sul..... grs. xx.
 Camph. pul..... grs. vi.
 Ginger pul..... grs. iii.

M. Ft. cht. No. 6. Sig.—One powder every four hours alternating with prescription No. 1. Plan of treatment as follows:

First.—Prescription Nos. 1 and 2 must be given on time, alternating each other, two hours apart, not omitting any doses; if patient is asleep, wake him up; thus keep up medication until the temperature reaches within one-half degree of the normal line; then you may stop medication at 10 P.M. and begin at 6 A.M. After the normal line has been reached and held for two days, you may drop to four doses of each powder per day for four days; after which you can drop to three doses of each per day, until the patient is able to be put upon full diet. Patient should be sponged off with tepid (slightly alkaline) water each evening, until the temperature has reached 100° F., or as long as it feels grateful to the sick.

Second.—Temperature of room must not fall below 68° F. regulated by a good thermometer.

Third.—Patient must lie quietly (not sit) in bed until all tenderness, gurgling, diarrhoea is gone; talking, laughing, or exertion retards the healing of bowels and should be avoided.

Fourth.—For the extreme weakness or profuse perspiration which sometimes sets in when the fever is rapidly declining, use the best old rye whiskey, made slightly bitter with gentian or cimicifuga, and give from one to two teaspoonfuls, as is necessary.

Fifth.—For diarrhoea use fl. ex. guarana in ten to fifteen-drop doses every three or four hours, and bromides for delirium. Any complication which may arise must be met by attending physician. Diet: Milk, toast, hard-boiled eggs, rice, crackers, coffee, lemonade.

To abort typhoid fever, give Prescriptions 1 and 2, alternating each other every two hours (*i.e.*, each in their place every four hours). Patient must lie down and be quiet from one to three days, owing to the severity of the attack, and take at least five doses of Prescriptions 1 and 2 per day for the first two days, then slowly diminish in number of doses as patient improves.

Ere this you have asked in your own minds what is cohothetra compound? As per analysis by Professor Powers, it is as follows (*verbat. et literat.*):

"PHILADELPHIA COLLEGE OF PHARMACY,
145 North Tenth Street. Founded, 1821.

PHILADELPHIA, November 25, 1831.

J. A. Davy, Esq., Troy, Ohio:

DEAR SIR—The substance submitted to me for analysis has been examined with the following result: It is a bright reddish-yellow liquid, having an aromatic odor, a pungent taste, an acid reaction, and contains (1) 78 per cent. by volume or 71.3 per cent. by weight of absolute alcohol; (2) 0.9098 per cent. of *nitrous ether*, corresponding to 21.8 per cent. of spirit of nitrous ether of the United States Pharmacopœia; (3) a small amount of the alkaloid morphia or morphine (too small for quantitative estimation); (4) very small amounts of the volatile oil of caraway and of resinous and coloring matter.

Respectfully yours,

FRED. B. POWERS,
Professor of Analytical Chemistry."

The resinous and coloring matter found by the professor is from the saturated alcoholic tincture of cohothetra, which composes the body of the compound, which seems to have no alkaloid. The compound now contains a small amount of carbonate of ammonia, which is used in preparing the cohothetra, which addition changes the color to red.

Cohothetra is indigenous to the United States, flowering in July; and is perennial.

The *Age* desired the knowledge and plan of treatment by which such good results were obtained, and as he was so gentlemanly in his last criticism, to withhold it from him would be unkind.

The *Age* now has the floor.

Faternally yours,

J. O. DAVY, M.D.

SPRINGFIELD, OHIO.

BIBLICAL ETHICS vs. PERCIVAL'S ETHICS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: From what has been said of late in the medical journals and in the daily press with regard to the nature and necessity of different codes of medical ethics one would imagine that physicians are a different order of beings from common men, and that they need a special and peculiar standard of morals by which to regulate their conduct. The old-fashioned idea of right and wrong seems to be lost sight of in most of the discussions. It seems to be taken for granted that there is need for a special standard of ethics for the physician, a standard which he himself has made and which does not apply to other men or other professions. The physician is not to ask, Is my conduct right and just according to the standard by which other men regulate their conduct? but Is my conduct in accordance with the Code of Medical Ethics?

Now in other professions and callings most intelligent men in this day hold that there is a code of ethics, commonly called Christian or Biblical, which binds all men and which is equally applicable to all under all circumstances, in all professions, in all ages. It is a code which is founded in right and justice. And, furthermore, any code of ethics which is not founded upon the principles of right and wrong as set forth in the Bible, and which does not conform to its teachings in this regard, should not be accepted as a rule of conduct. The teachings of the Bible and the dictates of an enlightened conscience are in harmony. Any code of ethics which leads a man to violate his conscience or do that which the word of God or his conscience tells him is not right and just is not to be obeyed.

In that portion of the world called Christendom Christian ethics must sooner or later prevail, even among physicians. Since the Reformation of the sixteenth century the fundamental principle of ethics, as applied to all men, no matter what their calling or profession, centres in the Golden Rule, "As ye would that men should do to you do ye also to them likewise," Luke vi. 31, and "Thou shalt love thy neighbor as thyself." To love thus and to act thus is the sum of human virtue.

Allow me to offer the following brief code of medical ethics as derived from the Bible. Does the physician want more than this standard by which to regulate his conduct?

I.—DUTIES OF PHYSICIANS TO THEIR PATIENTS.

The physician should treat his patient—

1. *With charity or love.*—"Love worketh no ill to his neighbor; therefore love is the fulfilling of the law," Rom. viii., 10. "Let all your things be done with charity," 1 Cor. xiv., 14. "Above all things have fervent charity," 1 Peter iv., 8.

2. *With conscientiousness.*—"He that walketh uprightly walketh surely," Prov. x., 9. "That which is altogether just shalt thou follow," Deut. xvi., 20. "What doth the Lord require of thee but to do justly," Micah vi., 8. "Herein do I exercise myself to have always a conscience void of offence toward God and toward men," Acts xxiv., 16.

3. *With faithfulness.*—"Doing faithfully whatsoever thou doest to the brethren, and to strangers," 3 John v.

4. *With honor.*—"Exact no more than that which is appointed you," Luke iii., 13. "See that none render evil for evil unto any man; but even follow that which is good, both among yourselves and to all men," 2 Thess. v., 15. "Abstain from all appearance of evil," 2 Thess. v., 22.

5. *With patience.*—"Be patient toward all men." "Let patience have its perfect work," 2 Thess. v., 14.

6. *With cheerfulness.*—"A merry heart doeth good like a medicine," Prov. xvii., 22. "A merry heart maketh a cheerful countenance," Prov. xv., 13.

7. *With candor.*—"A man that flattereth his neighbor spreadeth a net for his feet," Prov. xxxix., 5. "Wherefore putting away lying, speak every man truth with his neighbor," Eph. iv., 25.

8. *With helpfulness.*—"But to do good and to communicate forget not," Heb. xiii., 16.

9. *Without boasting.*—"Let another man praise thee and not thine own mouth; a stranger and not thine own lips," Prov. xxvii., 2. "The Lord shall cut off flattering lips and the tongue that speaketh proud things," Ps. xii., 3.

II.—DUTIES OF PHYSICIANS TO EACH OTHER.

Physicians should treat each other—

1. *With justice.*—"To do justice and judgment is more acceptable to the Lord than sacrifice," Prov. xxi., 3. "And what doth the Lord require of thee but to do justly," Micah vi., 8. "The way of the just is uprightness," Is. xxvi., 7.

2. *With peaceableness.*—"Let us therefore follow after the things which make for peace," Rom. xiv., 19. "Be at peace among yourselves," 1 Thess. v., 13. "He will surely reprove you if ye do secretly accept persons," Job xiii., 10. "Blessed are the peacemakers," Matt. v., 9.

3. *With unselfishness.*—"Look not every man on his own things, but every man also on the things of others," Phil. ii., 4.

4. *Not meddlesome.*—"For, brethren, ye have been called unto liberty, only use not liberty for an occasion to the flesh, but by love serve one another," Gal. v., 13. "Happy is he that condemneth not himself in the thing which he alloweth," Rom. xiv., 23. "Who art thou that judgest another man's servant? to his own master he standeth or falleth. Let every man be fully persuaded in his own mind," Rom. xiv., 4, 5. "Why is my liberty judged of another man's conscience," 1 Cor. x., 29.

5. *With generosity.*—"The liberal deviseth liberal things; and by liberal things shall he stand," Is. xxxii., 8. "The liberal soul shall be made fat," Prov. xi., 25.

6. *With honesty.*—"Ye should do that which is honest, though we be as reprobates," 2 Cor. xiii., 7. "Provide things honest in the sight of all men," Rom. xii., 17.

7. *With considerateness.*—"He that despiseth his

neighbor sinneth," Prov. xiv., 21. "Be patient toward all men," Thess. v., 13.

8. *Not quarrelsome.*—"Where envy and strife is, there is confusion and every evil work," Jas. iii., 16. "And be at peace among yourselves," 1 Thess. v., xiii. "Not of the letter but of the spirit, for the letter killeth, but the spirit giveth life," 2 Cor. iii., 6.

9. *The golden rule.*—"Therefore all things whatsoever ye would that men should do to you, do ye even so to them," Matt. vii., 12. "Be kindly affectioned one to another, with brotherly love, in honor preferring one another," Rom. xii., 10. "Finally, be ye all of one mind, having compassion one of another: love as brethren; be pitiful; be courteous," 1 Pet. iii., 8.

III.—DUTIES OF PHYSICIANS AS CITIZENS.

"Submit yourselves to every ordinance of man for the Lord's sake; whether it be to the king as supreme; or unto governors, as unto them that are sent by him for the punishment of evil-doers, and for the praise of them that do well. For so is the will of God that with well-doing ye may put to silence the ignorance of foolish men. As free, and not using your liberty as a cloak of maliciousness, but as servants of God. Honor all men. Love the brotherhood. Fear God. Honor the king," 1 Peter ii., 13-17. "Finally, brethren, whatsoever things are true, whatsoever things are honest, whatsoever things are just, whatsoever things are pure, whatsoever things are lovely, whatsoever things are of good report: if there be any virtue and if there be any praise, think on these things," Phil. iv., 8.

"Thou shalt love the Lord thy God with all thy heart, and with thy mind, and with all thy strength. This is the first and great commandment, and the second is like unto it. Thou shalt love thy neighbor as thyself."

Will not a diligent study of Christian ethics enlarge the understanding and elevate the feelings even better, perhaps, than a study of Dr. Percival's disquisitions?

Very truly yours,

CLERICUS.

COXALGIA AND SUBCUTANEOUS OSTEOTOMY.—In a paper in the July number of the *American Journal of the Medical Sciences*, Dr. H. R. Wharton records eight cases of coxalgia followed by marked deformity, in which eleven subcutaneous osteotomies of the femur were performed. The results obtained were most satisfactory, not only as regards the immunity from danger in the operation, but also as regards the correction of the deformities and restoration to use of comparatively useless limbs. The amount of constitutional disturbance following the operations was insignificant, as little, or even less, than that which follows a simple fracture of the femur; in no case was there excessive hemorrhage at the time of operation, nor did there follow in any case marked febrile reaction or suppuration; the wounds healed as ordinary tenotomy wounds, and by the end of the first week were generally found entirely closed, so that further dressings could be dispensed with. The facility with which the wounds healed in these cases can only be explained by their subcutaneous character, for although by the operation a compound fracture of the femur is produced, it must be remembered that the original puncture, which is made down to the bone by Mr. Adams's knife, is small, and that when the saw is introduced and cuts the bone, the wound is entirely filled by its shank, by blood and by dust from the sawn bone, so preventing the admission of air to the deeper parts. The results of reported cases bear strong testimony to the general safety of the operation, and there is no doubt that the selection of proper cases, and care as to the position at which the section of the bone is made, will render this operation one of the safest in surgery. The paper concludes with a full and careful discussion of the various details of the operation.

New Instruments.

A NEW SADDLE-CRUTCH.

By JAMES R. TAYLOR, M.D.,

NEW YORK.

It consists of a small saddle so arranged that it can be worn without inconvenience inside of the clothing. A pair of suspenders are attached to the saddle on each side, which terminate in steel hooks that are adjusted to the tops of the crutches. When the suspenders are fitted to the patient these hooks reach up to within about two inches of the axillæ, where the ends appear outside of the clothing, and are the only parts of the apparatus visible. The saddle is well padded to fit the perineum, and of such form that the patient rests upon it without discomfort while sitting.

When the crutches have been placed in the suspender hooks and the patient walks, the weight of his body is carried entirely upon the saddle, and without the crutches

reaching the axillæ, so that no discomfort is experienced, even in taking long walks. He swings easily between his crutches, taking long steps if he chooses, and, if otherwise strong, the weakness in his legs will not prevent him from exercising all that is necessary. The saddle-crutch possesses special advantages over the ordinary crutches, because the weight of the body is borne by the well-cushioned pelvic bones resting upon a comfortable saddle. While designed by nature for the purpose, the inconvenience and suffering attending exercise upon ordinary crutches with the weight of the body suspended upon cross-heads in the axillæ, is gotten rid of; and because the danger of injuring the axillary nerves and blood-vessels is avoided.

The device is designed for use with ordinary crutches, in all cases of lameness of the lower extremities necessitating artificial aid in walking, and has been employed with satisfactory results by several patients, male and female, who have suffered from fracture.

THE POISON OF LIZARDS.—Drs. Mitchell and Reichert find that the full-grown lizard will bite, and cause a wound that may prove fatal. Unlike that of other reptiles, its saliva is alkaline, not acid. A little injected into a pigeon caused the death of the bird (which was long, fat, and plump) in less than nine minutes.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 21, 1883, to July 28, 1883.

SUTHERLAND, CHARLES, Colonel and Surgeon, Medical Director, Military Division of the Pacific and Department of California. The leave of absence granted by S. O. 64, Headquarters Military Division of the Pacific, June 30, 1883, is extended two months. S. O. 168, A. G. O., July 23, 1883.

BAILY, JOSEPH C., Major and Surgeon. Assigned to duty as Post Surgeon at Fort Concho, Texas. S. O. 87, Headquarters Department of Texas, July 19, 1883.

APPEL, A. H., First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, with permission to apply for an extension of one month. S. O. 30, Headquarters Military Division of the Atlantic, July 20, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending July 28, 1883.

GATEWOOD, J. D., Past Assistant Surgeon. Detached from the New Hampshire and ordered to hold himself in readiness for sea service.

LEUCH, PHILIP, Assistant Surgeon. Detached from the Receiving-Ship Franklin and ordered to the New Hampshire.

SCOTT, HORACE B., Assistant Surgeon. Ordered to the Receiving-Ship Franklin, Norfolk, Va.

McMURTRIE, D., Surgeon. Detached from the Receiving-Ship Franklin and granted sick-leave.

WHITING, ROBERT, Past Assistant Surgeon. Granted one month's leave.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending July 31, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

A NEW THEORY OF THE CIRCULATION OF THE BLOOD IN THE ARTERIAL SYSTEM.—A Spanish physiologist, Dr. Ramon Turro, has put forth an ingenious theory as regards the mechanics of the arterial circulation, and we venture to offer an analysis of his views to your readers. The leading ideas are that the elastic fibres in the arterial walls cause dilatation rather than contraction—which latter is the result of the muscular action, and that the muscular walls of the arteries help to propel the blood along.

Turro first exposes what he calls the fundamental error of the reigning theory of the circulation, *i.e.*, that arterial elasticity causes diminution of the calibre of the tube.

It is the muscular and not the elastic tissue, says he, which causes retraction of the canal, as can be proved by removing a small piece of an artery and destroying the

vitality of its muscular elements. What is the result? The elastic tissue causes dilatation of the tube, although there is now no pressure to oppose its contraction. On the other hand, elasticity if it acts in the direction of arterial retraction cannot be brought into play until the pressure of the blood has distended the vessel. Now, this pressure, if it really existed, would seriously injure the delicate tissues in the same way that the violent introduction of a large cylinder would do. But the arterial system is not distended; on the contrary, it is contracted by the tonus of its muscular tissue, which is equivalent to saying that its elastic tissue tends to reopen the contracted vessels.

He then tries to prove that even without the presence of muscular tissue in the arterial walls the vessels could not be distended by the pressure of the blood. The sectional area of the base of the cone which represents the arterial system is eight hundred times as great as that of the summit or aorta (Vierordt). Can we, therefore, he says, suppose that the capillaries or base of the cone can be so contracted as not to admit one eight-hundredth as much blood as might enter at other times without causing distention? The theory states that arterial tension is caused by peripheral resistance; if the resistance did not exist this tension would be impossible. Very well, this resistance does not exist; on the contrary, that part of the arterial system which ought to be the smallest is precisely that which is the largest.

It is undoubtedly true that if the vessels tended to close, as the theory affirms, the force of the heart would be insufficient to drive the blood through them. This has been proved by experiments on contractile tubes. Nor is this all. If the conditions supposed by the mechanical theory to exist did so, the heart would have the weight of the whole organism to raise, for movements of elevation and depression are observed in all parts of the body synchronously with the heart's beat. In *résumé* we see that elastic tissue does not exist in the sense of arterial retraction, 1st, because it does not act at all; 2d, because, although the arteries have elastic walls, they act as if they had none; 3d, the supposition being true, the force of the heart would be inadequate to drive on the liquid column. After this general refutation of the mechanical theory of the circulation, Turro attacks Marez's theory in particular. According to Marez if we lessen peripheral resistance, the arteries send on the blood more easily, so that with augmentation of the venous flow we have diminution of arterial tension and increased activity of the heart's beat. Now these conclusions of Marez are negatived by the experiments of Ludwig, Thirz, Czorn, etc. (called *vitalistes*, in contradistinction to Marez and his followers, who are called *mechanicistes*), experiments which proved that blood-pressure could be raised at the same time that the frequency of the heart's beat was increased. The *vitalistes* have shown that when vascular paralysis is produced, stasis supervenes, because there is no force to drive the blood on to the heart, which seems to become feeble on this account. If the mechanical theory of the circulation were correct the vessels ought to urge on the blood and increase the venous flow, peripheral resistance being diminished. Instead of this we find the arteries more dilated than when we supposed them distended by eccentric pressure, the venous flow unchanged, and the rate of the heart's beat diminished.

Marez states that when arterial tension augments, the arteries above corresponding to the capillaries are gorged with blood. Now this arterial tension is only an *ens rationis*, besides, the application of the douche shows, that when the blood cannot pass along the capillaries as easily as before, the muscular tissue of the higher arteries relaxes (it is the artery which enlarges, and not the blood which distends it) and makes large channels for it. These changes of diameter are due to vaso-motor innervation. If we accept Marez's theory we must admit that the condition of the small vessels is

opposed to that of the large; the muscular tissue, however, of large and small vessels is continuous, hence the state of the peripheral circulation is in equilibrium with that of the arteries supplying the capillaries. To sum up, we find that the energy of the heart augments and diminishes with the venous flow, but we are not yet acquainted with the true mechanism which modifies its rhythm. Since the elastic tissue is retracted the more that the calibre of the vessel is diminished, we see that we have two forces at work, one tending to close, the other to reopen the canal; dilatation, then, is elastic tension which becomes free. Thus, while the theory affirms that the elastic tissue retracts because it has been distended, we say that it does so because it has been pressed together by the rhythmical action of the muscular elements. The blood having passed that part of the circulatory system where it is urged on by the cardiac systole alone, reaches the arteries possessed of muscular tissue, which contract behind the wave. Thus a slow vermicular movement creeps along. Another important factor is the elastic tissue, which dilates spontaneously at the place that the muscular tissue relaxes, and allows the blood to move along more freely.

Tonicity is a cohesion of the contractile plasma and is in inverse ratio to the quantity of blood which nourishes the muscular fibre. As soon as the flow of blood is diminished, the vessel contracts and adapts itself to the lessened stream. This adaptation is due to the nutritive modification of the fibre. Contraction and dilatation are only two phases of the mechanism of nutrition. The vessel will maintain itself in a permanent state of tonicity at a determined degree as long as a repairing assimilation will compensate for the incessant disassimilation which takes place in its contractile substance by the formation of new products due to its combustions. When equilibrium is disturbed by an excess of nutrition, tonus will be weakened by the nutritive relaxation of the muscular elements; when there is an insufficient amount of nutrition, movements of contraction will take place which may continue up to post-mortem contraction. When the flow is suspended the same disassimilation goes on, or the muscular substance coagulates and uses up its own substance to repair waste until its power is exhausted and it yields to the elastic tension. The contracted condition found in rigid muscle is only a development of the tonic cohesion normally present. Contractility resides in the muscle plasma—elasticity in its envelopes (sarcolemma, perimysium). The activity of the heart is also regulated by its nutrition; its energy must necessarily become less when less blood reaches it, because then its tonicity increases, its substance becomes impoverished, and its contractions become weaker each time. Cardiac rhythm is increased or retarded with the venous flow—energy is in inverse ratio to acceleration. It is in the chemical activity of the muscular substance of the heart that we must seek the secret of its rhythm.

Since the arteries contract when the amount of blood circulating in them diminishes, we must admit that there are rhythmical contractions, because the heart sends the blood on intermittently. The artery conducts onward the powerful impulsion imparted to it by the heart. How do the vessels dilate? The vessel or portions of vessels which are half bloodless retract in virtue of the increasing tonicity by which the plasma exhausts itself in producing contractions; but as contraction increases the elastic tissue is retracted and opposes resistance greater or less according to the contraction, like a spring. The blood exercises a pressure on the walls of the vessel for the reason that they are retracted. This pressure and elastic tension assist in passage of blood-plasma through the vessel, which being nourished, relaxes. Circulation is more active in brain than in crural artery, which seems to indicate that it is richer in muscular elements. The kidneys, spleen, etc., have rhythmical contractions which urge on the blood, so that we may speak not only of one circulation, but of several.

ITCH IN THE CAT.—A correspondent of the *British Medical Journal*, Dr. John Reid, writes as follows regarding a case of "acarus" in a cat: "The cat in question, when seen for the first time (it being a stray cat), was greatly emaciated, and died on the following night (January 5, 1883). The hair on one side of the face and neck, including the ear, was matted so as to resemble one large scab. The itch-insect and eggs were detected in large numbers. The cat's liver contained many abscesses of the size of a pin's head; the lungs, etc., appeared to be normal. Does the cat infect children, etc.? do these infect the cat? or is there mutual infection?"

ELECTRICAL FLANNEL FOR RHEUMATISM.—An electric curiosity which will soon be in the hands of charlatans has been invented by a Dr. Claudet. It is a flannel to cure or alleviate rheumatism. It contains, per kilo, one hundred and fifteen grammes of the oxides of tin, copper, zinc, and iron. A series of threads of this fabric is impregnated with these metallic products, and each series is alternately separated by raw threads. The flannel thus prepared constitutes a true dry pile. It is said to develop electricity by simple contact with the body, or better still, with the products of perspiration.

A NOVEL METHOD OF REMOVING A FOREIGN BODY FROM THE ŒSOPHAGUS.—Dr. Neuman was called to see a horse which was choking; the animal had been eating carrots. Dr. Neuman was unable to reach the foreign body with his hand. The horse's mouth was then opened, and held open by a mouth speculum. Then a common water hose, which was at hand, was passed through the speculum down the Œsophagus until the foreign body was reached. The water was turned on full force, and the obstruction disappeared.—*Journal of Comp. Medicine.*

TALMAGE ON DOCTORS.—We all like to be patted on the back once in a while, and brother Talmage does it in the following very vivid and unexaggerated manner: "Encourage all physicians. You thank him when he brings you up out of an awful crisis of disease; but do you thank him for treating the incipient stages of disease so skillfully that you do not sink as far down as an awful crisis? There is much cheap and heartless wit about the physician; but get sick, and how quickly you send for him. Some say doctors are of more harm than good, and there is a book written, entitled, 'Every Man His Own Doctor.' The author ought to write one more book and entitle it 'Every Man His Own Undertaker.' Do you think physicians are hard-hearted because they see so much pain? Ah, no! The most eminent surgeon of the last generation in New York came into the clinical department of the New York Medical College when there was a severe operation to be performed upon a little child. The great surgeon said to the students gathered around him: 'Gentlemen, there are surgeons here who can do this just as well as I can. You will excuse me, therefore, if I retire. I cannot endure the sight of suffering as well as I once could.' There are so many trials, so many interruptions, so many exhaustions in a physician's life that I rejoice he gets so many encouragements. Before him open all circles of society. He is welcomed in cot and mansion. Children shout when they see his gig coming, and old men, recognizing his step, look up and say, 'Doctor, is that you?' He stands between our families and the grave, fighting back the disorders that troop up from their encampments by the cold river. No one ever hears such hearty thanks as the doctor. Under God he makes the blind see, the deaf hear, the lame walk. The path of such is strewn with the benedictions of those whom they have befriended. Perhaps there was in our house an evil hour of foreboding. We thought all hope was gone. The doctor came four times that day. The children put aside their toys. We walked on tip-toe and whispered, and at every sound said, 'Hush!' How loud the clock ticked!

and, with all our care, the banister creaked. The doctor stayed all night and concentrated all his skill. At last the restlessness of the sufferer subsided into a sweet, calm slumber, and the doctor looked around to us and whispered, 'The crisis is past.' When, propped up with pillows, the sick one sat in the easy chair, and through the lattice the soft south wind tried hard to blow a rose-leaf into the faded cheek, and we were all glad, and each of the children brought a violet or a clover-top from the lawn to the lap of the convalescent, and little Bertha stood on a high chair with the brush smoothing her mother's hair, and it was decided that the restored one might soon ride out for a mile or two, our house was bright again. And as we helped our medical adviser into the gig we saw not that the step was broken or his horse sprung in the knees. For the first time in our life we realized what doctors are worth. In some of our minds among the tenderest of our memories is that of the old family physician."

THE CURE OF ONYCHIA AND INGROWING TOE-NAIL.—Dr. M. A. Veeder, of Lyons, N. Y., communicates the following: "For the cure of onychia and ingrowing toenail the following plan is simple and effective: Destroy the fungous granulations by means of strong carbolic acid, or silver nitrate, and then press back the diseased tissue away from the sharp edges of the nail by means of a piece of the ordinary felt-plaster so much used for corns, which is to be applied as follows: Get a piece large enough, such as that used for bunions if need be, and cut it the size of the exposed surface of the nail. Moisten the adhesive surface of the plaster, and apply it directly to the surface of the nail, pressing the margins of the felt firmly against the diseased parts surrounding the nail. It should be held in place until dry, when it will be found to be strongly adherent, and it may then be covered by a bandage, as a means of exerting still further pressure on the diseased parts. This dressing may require to be renewed repeatedly, at intervals of several days. The length of time required for a radical cure depending upon the extent to which the nail has been disintegrated, the cure not being complete until the parts destroyed are replaced by a fresh growth of nail substance."

THE GROWTH OF CHILDREN.—Some inquiries have been made by Dr. George W. Peckham, of Milwaukee, Wis., regarding the growth of children. The data were collected in Milwaukee. It seems that the density of population acts upon growth by affecting the health conditions, and by making the struggle for existence more intense. The greater height of males than females he finds is due to two causes: First, the arrest of growth of lower extremities in girls of about fourteen and a half years, boys experiencing no retardation in their growth; second, the falling off of the rate of growth in the bodies of girls at about the fifteenth year, and the termination of their growth at about the seventeenth year.

WHO WOULD NOT BE A DOCTOR?—Quite a number of our young men are studying for the medical profession. We do not wish to deter them from this laudable pursuit, for a physician's calling is one of the most honorable, ennobling, humanizing, and useful in the world. But all is not gold that glitters, and the following are some of the sweets of a doctor's life: If he visits a few of his patients when they are well, it is to get his dinner; and if he does not do so, it is because he cares more for the fleece than the flock. If he goes to synagogue regularly, it is because he has nothing else to do; if he doesn't go, it is because he has no respect for the Sabbath nor religion. If he speaks reverently of Judaism, he is a hypocrite; if he doesn't, he is a materialist. If he dresses neatly, he is proud; if he does not, he is wanting in self-respect. If his wife does not visit you, she is "stuck up;" if she does, she is fishing for patients for her husband. If he has a good turnout, he is extravagant; if he uses a poor one on the score of economy, he is deficient in ne-

cessary pride. If he does not write a prescription for every trifling ailment, he is careless; if he does, "he deluges one with medicine." If he makes parties, it is to soft-soap the people to get their money; if he does not make them, he is afraid of a *cent*. If his horse is fat it is because he has nothing to do; if he is lean, it is because he isn't taken care of. If he drives fast, it is to make people believe somebody is very sick; if he drives slowly, he has no interest in the welfare of his patients. If the patient recovers, it is owing to the good nursing he received; if he dies, "the doctor did not understand his sickness." If he talks much, "we don't like a doctor to tell everything he knows," or, "he is altogether too familiar;" if he don't talk, "*we like to see a doctor sociable.*" If he says anything about politics "he had better let it alone;" if he don't say anything about it, "we like to see a man show his colors." If he does not come immediately when sent for, "he takes things too easy;" if he sends in his bill "he is in a terrible hurry for his money." If he visits his patients every day, it is to run up a bill; if he don't, it is unjustifiable negligence. If he orders the same medicine, it does no good; if he changes the prescription, he is in league with the druggist. If he uses any of the popular remedies of the day, it is to cater to the whims and prejudice of the people, to fill his pockets; if he don't use them, it is from professional selfishness. If he is in the habit of having frequent consultations, it is because he knows nothing; if he objects to having them, on the ground that he understands his own business, "he is afraid of exposing his ignorance to his superiors." *If he gets pay for one-half his services* he deserves to be canonized. Who wouldn't be an M.D.?—*The Hebrew Standard.*

THE EMPRESS OF GERMANY.—The wife of the American Minister at Berlin, Mrs. Sargent, in a letter describing a call upon the Empress, said: "Her Majesty surprised me by asking about my daughter Lizzie. She had heard that Lizzie began the study of medicine in California, and was now continuing it in Zurich. 'We are much interested in medicine,' the Empress added, and then spoke of the civil war in America and the Franco-Prussian war, saying that the Germans had gained much valuable information from the Americans as to the treatment of sick and wounded soldiers, which was put to good use in their last war."

A CASE OF GLOSSO-LABIO-PHARYNGEAL (OR BULBAR) PARALYSIS WITH THE LESION IN THE CEREBRAL HEMI-SPHERES.—Dr. C. K. Mills, at the June meeting of the College of Physicians of Philadelphia, said that the present was a good opportunity to put on record an observation on cerebral glosso-labio-pharyngeal paralysis. It is well-known that this affection is usually attributed to degeneration of the cranial nuclei; in fact, it is often called "bulbar paralysis." A patient presenting the oral, labial, lingual, and pharyngeal symptoms of this disorder, had died about two years before at the Philadelphia Hospital. Examination showed no lesion of pons or medulla. Along the outer border of both lenticular nuclei, and extending into the external capsule and claustrum, were long, narrow, and somewhat irregular areas of degeneration; softened or broken-down districts surrounded by walls of harder, darker tissue. Kirchoff and others had since reported similar cases, but up to the time of making the observation he had never seen such a case reported.

THE SIXTH AND SEVENTH CRANIAL NUCLEI.—At a meeting of the College of Physicians of Philadelphia, June 6th, Dr. Harrison Allen called attention to the curious apparent discrepancy between the anatomical and physiological relations of the sixth and seventh cranial nuclei. He said: "The cranial nerves at their nuclei of origin and in the course of their intrinsic fibres may be involved in diseased action. It would seem to be more than a coincidence that the nuclei of the ninth, tenth, and eleventh nerves are arranged in a definite series, forming the trineural fasciculus; and that the nerves themselves are

associated in function. But this line of reflexion is useless when applied to the nuclei of the sixth and seventh nerves. These nerves appear to have no function in common, and yet they arise, in part at least, from the same nucleus. In their range of variation they have no relation with one another; nor in any animal known to the writer does the sixth nerve spring from the facial trunk, but always (in variations from the human type) from the third. The third, fourth, and sixth nerves are naturally associated; but no reason is assigned for the withdrawal of the nucleus of the sixth from the mid-brain; where the nuclei of the third and fourth nerves lie, to the hind-brain, where it is in association with an alien, namely, the seventh. Associated paralysis of the third, fourth, and sixth nerves is common; but paralysis of the sixth and seventh is rare.

HUMAN PARASITES.—Dr. George Sutton, in an article in the *Cincinnati Lancet and Clinic*, gives the following list showing the principal parasites which infect the human system:

Microzymes.—Micrococci: Probably of small-pox, cow-pox, measles, scarlatina, varicella, erysipelas, syphilis, gonorrhœa. Bacilli: Probably of typhus fever, typhoid fever, tuberculosis, anthrax, leprosy. Vibrio. Filaria: Probably of elephantiasis. Spirillum: Probably of relapsing fever. Bacteria: Probably of septicæmia.

Entozoa.—Vermes—Cestoda: Probably of *tænia eliptica*, *tænia flavo punctata*, *tænia medio canellata*, *tænia nana*, *tænia solium*, *tænia bothriocephalis candatus*, *tænia bothriocephalis latus*. Nematoda: Probably of *ascaris lumbricoides*, *ascaris mystax*, *oxyuris vermicularis*, *filaria medinensis*, *dochmius duodenalis*, *trichocephalis dispar*, *trichina spiralis*. Trematoda: Probably of *monistoma*, *distoma*.

Epizoa.—Insects—Acarus *scabei*. Pediculida: Probably of *pediculus capitis*, *pediculus vestimenti*, *pediculus tabesentium*, *pediculus pubes originalis*. Pulix: Probably of *pulix irritans*, *pulix penetrans*. Ixodia: Probably of *ixodes americanus*, *ixodes numarias*, *ixodes erenatus*.

Undoubted vegetable parasites and their diseases.—Microphytes—*Achorion schonleinii*: Probably of favus. *Trichophyton tonsurans*: Probably of porrigo scutulate. *Microsporon andonini*: Probably of porrigo decalvans. *Microsporon mentagrophites*: Probably of mentagra. *Microsporon furfur*: Probably of tinea chloasma.

SEA-BATHING.—At the present time, when the sea-bathing season is about to commence, it may be useful to recall the chief general indications and contra-indications which respectively sanction and forbid bathing in the sea. "Shall I bathe?" This is a question which thousands of health-seekers will be asking of their doctors during the next few weeks. While the stimulus of a fresher air, of change of scene, and of new occupations, together with rest from accustomed work, are the elements from which the weakly, the worn, and the worried reap physical and mental restoration in a sojourn on the sea-coast, it is unquestionable that bathing in the open sea is, in itself, a powerful restorative agency, which many persons may employ with very great advantage. The universal experience of our race, through unnumbered ages, has shown the value of sea-bathing in both preventive and curative medicine. A good rule, laid down by an experienced physician, is this: In all cases showing impaired functional powers, without any manifestation of inflammatory symptoms—in short, in those cases in which the exhibition of alteratives and tonics is indicated—sea-bathing, may, with proper precautions, be resorted to; it is contraindicated in persons of plethoric habit of body, in cerebral congestion, in organic disease of the heart, in aneurism, and in all persons who have the inability safely to encounter a comparatively severe shock; while it is also to be forbidden at certain periods in which the female constitution is not prepared for the application of powerful remedies. Because it tends, in certain conditions of impaired health, to cause determination of blood to the viscera. Bathing in the open sea is

generally unsuitable for persons disposed to congestive disorders of the lungs, kidneys, liver, and brain. Albuminuria, advanced anæmia, and a liability to hæmoptysis, are also conditions with are usually accepted as contra-indicating sea-bathing. It is hurtful to bathe babies in the sea; children under two years of age are too young to bear with advantage the comparatively severe shock of a cold sea-bath. In old age, when the bodily powers are unequal to a vigorous reaction, sea-bathing may do much harm, especially in the subjects of extreme arterial degeneration. In suitable cases, and under proper precautions as to time of bathing and duration of exposure, a daily bath in the open sea is a valuable restorative. In individuals who are fairly robust, it is a stimulant alterative and tonic, promoting appetite, tissue-change, and excretions, and bracing up the nervous, vascular, and muscular systems. Sea-bathing is especially useful as a powerful and unsurpassed tonic in delayed convalescence from acute diseases, in many chronic affections, and in persons whose strength has become enfeebled by injurious excesses, by mental strain, or by unhealthy occupations.—*British Medical Journal*.

AWAY WITH THE SPOON.—A contemporary proposes to get rid of the use of "spoonfuls" as doses by the following expedient: "Let each bottle (vial) be provided with a strip of paper pasted on, which strip is accurately divided with as many lines (marks) as the bottle contains doses to be taken, the lines to be numbered, beginning with the topmost, and let the directions read: Take one eighth (fourth, twelfth, etc.), part, etc., as the direction shall run, or, perhaps better, take one division, etc. The strip to reach from the bottom of the bottle (vial) to the top of the liquid, not farther."

PROFESSOR VIRCHOW AND THE SWISS PILL.—Professor Virchow has fallen under the displeasure of the Congress of German Physicians, a society which meets annually to take cognizance of medical ethics and allied matters. He has been charged with giving a testimonial to a secret remedy, the *pilulæ helveticæ* of a Dr. Brandt, of Schaffhausen; and doubtless many of our readers have themselves received the laudatory notices which accompany these famous "pills," the distribution of which has not been limited. Virchow, in a letter to the *Berliner Medizinische Wochenschrift*, marvels at the amount of displeasure which he has apparently incurred. He says that he received some of the *pilulæ helveticæ* last winter, with a letter from Dr. Brandt asking him to give them a trial. Some time afterward came another appeal, and, being himself in the need of such a remedy, he tried their effect on himself. The result was so satisfactory that he penned a few lines to the inventor, which the latter forthwith published without Virchow's sanction, pleased, no doubt, when such testimony came from so high a quarter. From that time Virchow has had no peace—letters and circulars, signed and unsigned, have been addressed to him complaining that he was violating the ethical law in giving a testimonial of a secret remedy; and this has culminated in the remonstrance addressed by the chairman of the committee of the *Aerzte-vereinbund*. The committee also procured an official analysis of the pills, which, however, only went to show that their composition was nothing very extraordinary. Virchow denies that he ever gave a testimonial at any time for these or any other pills. He withdraws from the Bund, and appeals from its arbitrary action to his medical brethren at large to pass a judgment free from the paltry and narrow trades-unionism which characterizes this act.

ANSWERS TO MEDICAL CORRESPONDENTS.

Dr. S. W. G., Iowa: Yes, two grains of strychnia was a large dose for that baby.

No, his convulsions were not entirely due to teething.

No, it does not make any difference if you did pass second in your class when you graduated; the law will hold you just as responsible.

Yes, before a jury it would perhaps be a mitigating circumstance that you had graduated without ever seeing a case; but the father of the child could not prosecute your medical college.

THE PRESENT ASPECT AND FUTURE PROSPECTS OF MEDICINE.

AN ADDRESS DELIVERED AT THE FIFTY-FIRST ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.¹

By A. T. H. WATERS, M.D., F.R.C.P.,

SENIOR PHYSICIAN TO THE ROYAL INFIRMARY, AND PROFESSOR OF MEDICINE IN UNIVERSITY COLLEGE, LIVERPOOL, PRESIDENT OF THE ASSOCIATION.

GENTLEMEN: I esteem it an honor of no common kind to be elected President of the British Medical Association, and to be called upon to take the chair at one of its annual gatherings; and to me the honor has a special value, for I can look back on many years of close relation with the society; it has been the means by which I have formed friendships whose importance I cannot overestimate, and its meetings have been among the most interesting circumstances of my life. Your kindness, therefore—the kindness of my fellow-residents and of the Association at large—in placing me here to-day, deserves my warmest thanks, and will always be held in grateful remembrance.

Twenty-four years have passed since the Association met in Liverpool to celebrate its twenty-seventh anniversary. These years have been marked by the uninterrupted prosperity of our society, by a large increase in our numbers, and an increasing interest in the proceedings of our annual gatherings. With reference to our success, it may, perhaps, be sufficient to say that, whereas at that time and up to the year 1866 we numbered about twenty-three hundred members, we are now ten thousand strong. May the future progress of the society be ever in accordance with its experience of the past; and may he who shall open its next session in this city be able to say, with as much truth as I can to-day, that the Association has increased in strength with its increased years.

But, gentlemen, while we congratulate ourselves on the success of our efforts in connection with this large Association, let us never forget that we are all members of a still larger body—that we belong to the great commonwealth of medicine, which knows no distinction of race, or clime, or people; and that, while it is our duty, and should always be our aim, to promote the special objects for which our society was founded, our highest duty and our noblest aim should be to foster the general interests of medicine, and to endeavor to advance it as a science and as an art; and, in the few remarks which I have to address to you on this occasion, I purpose to dwell, very briefly, on some of those points which seem to me worthy of our attention with reference to the present condition and future prospects of our profession; for, although there are many topics of local interest to which I might refer, all that relates to Liverpool—its medical history, its hospitals, its school of medicine, its University College, its public buildings, its river, and its docks—has been so well treated of in some recent numbers of our *Journal*, that any further observations on the subject are altogether unnecessary.

When last we met, in Worcester, we celebrated our jubilee, and it was well to look back on the period which had elapsed since our society was founded, and to refer with satisfaction to the good work which it had done, and

the progress which medicine had made during the previous fifty years. And while echoing to-day all that was then so ably expressed, I think it would be well if we were to consider that we have now entered on a new phase—that we have taken, as it were, a new departure, and that with the great advantages we possess we should, as a society, and also as a profession, strive to develop our science more rapidly in the future than it has been developed in the past, and that our progress should be more marked in all that relates to the higher aspirations of our calling.

Nor are there wanting signs which point to the probability of such a consummation. We now see a higher standard of medical education insisted on; we see, on all sides, the inductive method of investigation brought to bear on the great problems of medicine; more and more we see dissatisfaction with our present uncertain and inexact knowledge; and we cannot doubt that the observations which are being carried on, and especially those which are being conducted under the auspices of our Collective Investigation Committee and of the Society for the Cultivation of Medicine by Original Research, will before very long bear fruits, and lead to generalizations of the most important kind.

To my mind there is nothing in the present aspect of medicine more satisfactory, or more likely to raise it from the region of empiricism and place it on a higher scientific level, than the endeavor now being made to render our knowledge more definite and exact; and if I were to point to one circumstance which, in my opinion, has, probably more than any other, contributed to this result, I should say it was the introduction into our practice of *instruments of precision*. These have furnished us with means by which the senses may be placed in immediate relation with the actual phenomena of disease, and these phenomena are sometimes of so simple a character, and yet so indicative of the general morbid state, and require so little mental analysis, that the very tyro can almost read their significance.

No more important step was ever made in practical medicine than that of the application of physical principles to the diagnosis of diseases of the chest. In what condition would now be our knowledge of diseases of the lungs, had the researches so largely associated with the name of Laennec never been made? In what condition was the knowledge of cardiac diseases before the investigations and experiments of the physiologist gave us definite information with reference to the movements of the heart, the action of its valves, and the causes of its sounds? The differentiation of lung and heart affections by the aid of physical inquiry, the possibility of making an exact diagnosis without investigating one single general symptom, constitute a triumph for medicine which is not to be surpassed in the practical application of scientific principles in any other department of human knowledge; and we must not forget that this marked advance has been achieved in a comparatively short space of time, for it was not till 1819 that Laennec gave his observations to the world.

What can be more striking than the results of physical inquiry in pulmonary or cardiac diseases? Let us suppose a student in medicine following, for the first time, a competent teacher through the wards of a hospital. He sees him stop at the bedside of a patient suffering from one of these affections; he watches him as he makes his examination; he hears a few leading ques-

¹ Held in Liverpool, July 31, and August 1, 2, and 3, 1883

tions put, he sees a few gentle blows struck; a brief application of the stethoscope; and then, without any hesitation, the physician, turning to his class, tells of the nature of the case—that there is consolidation of a lung; effusion into the pleura; disease of a particular valve of the heart, hypertrophy of its walls, or degeneration of its fibres. He speaks of the mode of origin of the affection, the course it will probably take, and the issue that will come. Our student is struck with astonishment at the apparent facility of the diagnosis, and the rapidity with which it has been made. He watches the progress of the disease, and he finds becoming developed the conditions which were foretold; and (if, unhappily, the case terminates fatally), on a subsequent day, following his teacher to the *post-mortem* theatre, he sees the body of the patient submitted to examination; he sees revealed by the scalpel the condition which exists. He sees that there is consolidation of a lung; effusion into the pleura, valvular disease of the heart; hypertrophy of its walls, or degeneration of its fibres; he sees, in fact, a verification, in its minute details, of the diagnosis that was made, and he is apt, perhaps, at once to conclude that medicine is one of the most exact of the sciences.

It would be well if in all departments of medicine there were the same facilities for exact diagnosis as in diseases of the heart and lungs; but what the application of acoustic principles has done in these affections, the application of chemical principles, and the use of the microscope, the ophthalmoscope, the laryngoscope, and the sphygmograph, have in a measure done for the diseases of some other organs. And may we not hope that, with reference to the diseases of the nervous system—the most obscure of all which come under the notice of the physician—the researches of the present day, and the attempts now being made to clear up our knowledge of the physiology of the brain, and to localize its various functions, may be followed by results which will add largely to our powers of differentiating nervous affections, and of successfully treating them?

Again, in referring to instruments of precision, let me observe how important are the results which have followed the use of that instrument which, when the Association last met here, was scarcely ever used in this country, but which is now the constant companion of every practitioner—the clinical thermometer. How valuable is the information which it gives! How intimately does it place that important factor of fever—increased temperature—under our observation! Without attempting to discuss the relations of heat to the other phenomena of fever, I may observe that, in a large number of cases of disease, the measure of the temperature is undoubtedly the measure of the danger; and that the immediate recognition of its rise to an inordinate extent is the first step toward the application of means on which the life of the patient may depend. Were this the proper occasion, I should like to dwell on the great value which the scientific use of the thermometer has been, and is likely still further to be, to the practical physician. Not only has it enabled him to recognize conditions of hyperpyrexia fraught with extreme peril, and thus to use at the right moment measures for reducing temperature which have been followed by the most beneficial results; not only has it afforded a means by which the constant attendant on the sick can ascertain the development of serious symptoms; but its further application, and the recognition, by its use, of the special oscillations of temperature which characterize some diseases, have enabled the physician to differentiate between affections in which other means of diagnosis have been insufficient; while, by still more extended observations with the instrument, we shall perhaps be able to explain, more fully than we now can, the causes which underlie the variations of temperature which are so marked a feature of some affections; and possibly this knowledge may influence beneficially our treatment of them. And, in referring to this

subject, I cannot refrain from alluding to the fact that it was a Liverpool physician, Dr. Currie, who, early in the present century, was the pioneer in the use of cold applications to the surface of the body in the treatment of fevers; and, although Currie's practice fell into disuse, the merit of initiating a method of reducing temperature, which the use of the thermometer has enabled us in the present day to place on a more successful basis, may, I think, be fairly claimed for him.

How often has the use of the laryngoscope enabled the practitioner to recognize the true bearings of certain laryngeal symptoms, and to differentiate between organic disease of the larynx and the results of pressure from a thoracic tumor! How often has it enabled him to decide on the nature of a laryngeal growth, and the possibility or otherwise of successful medical or surgical treatment! How much do we not owe to the introduction of the ophthalmoscope—an instrument which has literally thrown a flood of light on the affections of the eye, and may be said, indeed, to have revolutionized the whole practice of ophthalmic medicine; while, by enabling us to recognize certain conditions of the eye, and to interpret their significance with reference to other morbid states, it has materially aided the work of the general physician.

The sphygmograph is an instrument which, though largely employed in hospital work, has not hitherto found its way into general use. It cannot be said to have had much influence on our practice; but I think we often derive important indications from it with reference to the state of the arterial system and the degree of arterial tension which exists; and possibly by a more frequent employment of it we might be able to recognize, at an earlier stage than we now can, those manifestations of incipient disease which frequently pass unnoticed, and therefore untreated. Further, in certain acute diseases, the sphygmograph often gives indications which are important in regard to prognosis. The hyperdicrotism of the pulse, as shown by the instrument, may indicate the extreme gravity of a case which other symptoms fail to point out.

I am glad to see that in the Section of Medicine a discussion is to take place on the subject of arterial tension, and I hope that some valuable information may be elicited from it. I believe that important results may be expected to follow from more exact observation on the condition of the arterial system.

The great results which have followed the application of physical principles to the recognition of disease, constitute the common-places of medicine of the present day; and perhaps I ought to offer some apology for dwelling upon them; they are, nevertheless, the great facts of medicine, they are the facts to which we can point as showing the scientific basis of our art, and their value can be appreciated only by those who are engaged in the practical application of therapeutics. They are, moreover, the main guarantee which we have for progress in the future; for who shall doubt that the next half century will be more fertile in the production of instruments of precision, and in bringing scientific principles to bear on the work of the physician, than that which has just passed? Who shall doubt that as the result of the more rigid application of the inductive method of research, and more careful and combined clinical investigation, our powers of generalizing on disease, and of differentiating between the variations which it presents, will be largely increased; that diagnosis will be more easy, and treatment more successful?

In considering the standpoint of medicine, we should always bear in mind that medicine must be judged by the therapeutic results which it achieves; and in proportion as we can show that the researches of the physiologist, the pathologist, and the chemist, and the application of scientific principles, have enabled the physician to deal more successfully with disease, to anticipate its development, to recognize its earliest symptoms, to mitigate its severity,

and reduce its rate of mortality, so do we establish for our art a claim on the confidence and gratitude of mankind; and in this respect the present state of medicine shows no slight advance on the past, and promises a more rapid progress in the future. The past five and twenty or thirty years—not to go further back—have been marked by the general development of views with reference to many diseases, such as have largely and beneficially influenced our treatment of them; and as I took an illustration of the value of physical investigation from diseases of the chest, permit me to refer again to some of these affections in speaking of the question of treatment. With regard to the affection which we term pneumonia, have we not seen the introduction into practice of a mode of treatment which has deprived the disease of much of its terror, and greatly reduced its mortality? Whatever be the views which we entertain of the nature of pneumonia, the important fact remains that we may enumerate among the successes of medicine of the present day a large reduction in the mortality from the affection.

Again, the recent development of the practice of tapping the chest in pleuritic effusion, an operation comparatively rarely performed thirty years ago, is, in my opinion, a very marked improvement in therapeutics. Those who have carefully watched the progress of medicine in this matter, know full well how great have been the changes which have taken place within the last quarter of a century, and especially since the introduction of the aspirator. It is impossible to refer to all those to whom we are indebted with reference to this subject, but Trousseau, as a pioneer, and Bowditch, whose large experience and satisfactory results exercised so beneficial an influence, I must not pass over; while there are many in this country to whom we owe no less a debt of gratitude. There is, perhaps, from the facility with which tapping may be performed, and the almost entire absence of risk when it is properly performed, a fear that it may sometimes be resorted to unnecessarily. But, from what I may term a somewhat large experience in the operation, I can speak with confidence of its value and safety in both acute and chronic effusions; and I cannot but think that, as the result of the early performance of the operation, we shall see, every year, fewer of those cases of deformed chest which so frequently follow neglected pleuritic effusion.

How satisfactory have been the practical results which have followed the researches that have been made, within the past half century, into the nature of continued fevers! It is now about forty years since Stewart (whose recent loss we have to deplore) published his investigations in typhus and typhoid, and showed their distinct and separate individuality. Other laborers have since worked in the same field, and have established, beyond a doubt, the facts which he then demonstrated, the knowledge of which has largely tended to the prevention of these affections, and enabled us to trace to their source many outbreaks which, in former times, would have been involved in mystery. Nor can we point, perhaps, to any one circumstance which has had a more beneficial influence on the treatment of these diseases than the recognition of the pathological changes by which they are characterized. The precautions which we consider imperative during convalescence in the one disease—precautions which may be, in large measure, neglected in the other, are but the outcome of the careful investigations which have been made into the morbid changes by which the two affections are attended. And if we have abandoned the idea that these fevers can be cut short by any measures, or the administration of any drug; if we have no faith in any specific line of treatment, and are, for the most part, content to watch our patients carefully, and to guide them, as it were, through their attacks, this is not scepticism—it is the result of a more intimate knowledge of these diseases, of a better acquaintance with their natural history, and a better appreciation of their pathological changes. We

wait for further insight into their essential nature, and we are not without hope that fresh discoveries will give us increased power, in regard both to their prevention and their treatment.

It is impossible to enumerate the various affections in which there is a marked improvement in treatment, and those which I have referred to must be considered simply as illustrations of my position; but while I speak with satisfaction on this subject, I must not forget to mention that, in the midst of many successes, we have instances of, I will not say actual, but comparative failure. Our knowledge of the pathology of some affections remains very imperfect, and our therapeutics are in some respects very unsatisfactory. Although rheumatic fever is one of the most common diseases, it must be confessed that we are ignorant of its pathology. During the past few years there has been introduced into practice a mode of treating the disease by the compounds of salicylic acid, which has met with general adoption, and has been largely successful. I can add the testimony of my experience in its favor; but still, with all the opportunities which we possess of studying the affection, we are as yet unable to give any satisfactory explanation of its essential nature.

Again, how unsatisfactory is the knowledge we possess with reference to the pathology of diabetes! We have long recognized its clinical features, and we are often able to modify its course, and mitigate its symptoms; but of its real nature we are ignorant, and nothing has tended to show this more than the discussion recently carried on at one of our societies. But this confession of our ignorance is one of the most promising features of our day, it is that which gives us assurance that every effort will be made toward increased knowledge in the future. Whence comes this want of success in the investigation of the nature of diabetes? We have approached it from the physiological side, from the chemical side, and from the pathological side, and have failed. Can we hope that by combined observation of its clinical features, of its life-history, and its relation to families and individual peculiarities we may elucidate its nature? May we hope that it is one of those subjects which will be inquired into, and the problems of which will be solved by the labors of our Collective Investigation Committee? I recommend it to their consideration.

And here I must express the great satisfaction with which, in common, I am sure, with every member of the Association, I have seen the establishment of this Collective Investigation Committee, how strongly I feel that it is capable of accomplishing most valuable work, and how much I think we are indebted to Professor Humphry for initiating the movement. Doubtless, a large part of the work of the committee will consist in collating facts with reference to specific diseases; but there is one line of inquiry which, I trust, will receive from it a share of attention. I mean the consideration of the points of difference between functional disturbances, and the early symptoms of organic affections. How difficult is it sometimes to say, when some slight symptom presents itself, and when no objective signs of organic disease can be discovered, whether that symptom indicates incipient structural change or mere functional disarrangement! Upon the right appreciation of the phenomenon, however, the safety of the patient may depend; for, although we stand almost powerless to arrest the course of confirmed structural changes, there can be no doubt that, could we recognize the earliest steps in these changes, could we see clearly the points of departure from normal conditions in various chronic and hitherto incurable maladies, we might do much to check these alterations of structure, and prevent the further progress of the disease.

In an investigation of this kind, our hospital work is comparatively useless. There we are brought into relation, for the most part, with disease already well marked—disease which has produced its easily recognizable re-

sults; and if patients present themselves with slight symptoms, they perhaps soon recover, and are lost sight of. It is in the daily work of private practice that observations such as I have referred to can alone be satisfactorily made; and it is, therefore, to the great bulk of practitioners throughout the country that we must look for aid in this matter. It involves a lengthened study of each individual case; a close watching, not for weeks or months, but for years; and perhaps the facts gathered in a lifetime might be but few. It relates to the consideration of subjective symptoms which we cannot accurately estimate with our present physical means, but which are intimately associated with individual peculiarities and idiosyncrasies, and often form the most important elements in our diagnosis, prognosis, and treatment. It may be that, with more refined instruments of precision and greater scientific knowledge, we shall bring many of these symptoms within the range of physically recognizable facts; but, in the meantime, inquiries such as I have referred to may materially aid us.

But, gentlemen, of all the questions which now engage the attention of the pathologist and physician, there is no one which surpasses in importance that which relates to the dependence of certain diseases on micro-organisms. The subject is one of the greatest possible interest, and fraught with bearings of a practical character which already have had, and are doubtless destined still further to have, a vast influence on the prevention and treatment of disease. The establishment of the fact that *pébrine*, chicken-cholera, and splenic fever depend on the presence of specific microbes, and that relapsing fever has associated with it, if not indeed causing it, a like organism, must be classed among the most striking discoveries of the present day, and undoubtedly mark an epoch in the history of pathological science; while the gradually accumulating evidence that tuberculosis is the result of a parasitic element seems likely to lead to its being placed in the same category as those affections the pathology of which appears now to be clearly established. Moreover, the brilliant results which have followed the process of attenuative culture of the virus of some of the affections to which I have referred, and the protective influence of vaccination by these attenuated fluids, as carried out by Pasteur, lead us to hope that, by further researches in the same direction, we may yet discover some means for checking the ravages of tuberculous and other allied diseases, as certainly as the great discovery of Jenner has enabled us to check the ravages of small-pox.

Nor is it possible, perhaps, to point to any single fact in connection with the practical application of science which is more striking than that of the relation of disease to minute organisms. The whole subject has been evolved from the researches of a few naturalists who studied the smallest of living beings. What possible use, might it not have been said, could investigation of this kind have in reference to the maladies either of man or the lower animals? And yet we have seen that these studies of minute life have led to the prevention of a disease which threatened to destroy the source from which we derive one of our staple products of manufacture; they have been largely instrumental in checking the ravages of a malady which is so fatal among the flocks and herds of various countries; they have led to the introduction into the practice of surgery of a mode of treatment, the beneficial effects of which it is not for me to dilate on; and, lastly, it seems likely that they will materially alter our views with reference to some of the most serious diseases to which mankind is subject.

These facts tend to show on how wide a basis the science and art of medicine rest, and how closely their advance is mixed up with, and dependent upon, the progress of other sciences. In truth, there is nothing in the whole range of nature which the physician may not make use of for the purposes of his work.

Of the many problems which await solution in con-

nection with the subject which I have just considered, no one is more pressing than that of the dependence, or otherwise, of pulmonary consumption on the bacillus which has been so largely found, not only in the morbid deposits which result from the disease, but in the expectoration of phthisical patients. Should it be found that in all cases of genuine tubercular phthisis the bacillus tuberculosis is present, and should future researches show that the disease is caused by the parasite, a solidity will be given to the pathology of the affection, and perhaps the therapeutics of it will be materially aided. Speaking from clinical experience, I cannot but conclude that the disease to which we give the name of phthisis has more than one mode of origin. Further investigation will perhaps clear up the doubt which exists on this point; and here I should like to observe that there are some affections of the lungs which closely resemble, in their clinical features, acute phthisis, and yet which, under careful treatment, do not go on to a fatal issue. Of such cases I have now seen several. Their general symptoms, their physical signs, their temperature-ranges made me conclude that I had to deal with cases of acute pulmonary tuberculosis, and I have expected a fatal result, but recovery has taken place. These cases occurred before attention was directed to the presence of bacilli in the sputum of phthisical patients, and no examination of this secretion was made. In instances of a similar kind, we shall now be able to use this method of investigation, and possibly it will afford a valuable means of differential diagnosis, and enable us to give, in cases where the bacilli are absent, a more favorable prognosis than the general symptoms would otherwise warrant. I may say, in regard to the cases to which I have referred, that they were treated by free nutrition, generally the exhibition of quinine, and a somewhat liberal quantity of alcoholic stimulants.

The great point which remains to be decided, and which I hope the discussion which will take place at this meeting will help to decide, is, whether the so-called *bacillus tuberculosis* is the cause, or the consequence of the tuberculous disease.

I have spoken of the advance which medicine has made as the result of the application of scientific principles, and an improved knowledge of physiology and pathology; and I would further remark that the past years have been fertile in the introduction of substances which are of the highest value to the physician in the actual treatment of disease. The bromide compounds, chloral, croton-chloral, the various forms of pepsine and pancreatine, the salts of salicylic acid, may be enumerated, among others which the chemist has furnished for our use; and, while we may perhaps feel that he will best serve the ends of medicine who shall teach us how to employ most successfully the remedies we already possess, and while we would deprecate the incessant desire for the introduction of new chemical compounds, let us by no means discourage the laudable ambition of enriching our Pharmacopœia with agents of sterling value. We must never forget that, in addition to the useful drugs to which I have already referred, the present age has given us, by the agency of the chemist, means by which we can annihilate the pangs of the most painful manipulations of surgery, and obviate the tortures formerly incidental to all operative procedures.

In the face of such a fact as this, we may be pardoned if we express a doubt whether we have arrived at the limit of our therapeutical discoveries, and whether we may not hope that the labors of the chemist will, in the future, give us new elements for our use, or that some of those compounds which now possess only a scientific interest may, in course of time, pass into the hands of the practical physician, and add to his powers of controlling certain forms of disease.

It is not for me to speak of the triumphs of modern surgery, and the successful results which have followed the application of scientific principles in this great de-

partment of medicine. We are apt, perhaps, to conclude that it is here that the most striking advances have been made; but I venture to think that, in proportion to the difficulties which have had to be solved at the hands of the physician, medicine pure has made a progress as great as that which has characterized the sister art of surgery, or, indeed, any other art in which science has been brought into practical application. Consider how difficult are the problems which disease presents; the complexities of organic life; the many peculiarities and tendencies of each individual man; the inherited liabilities; the subtle influences of habit, of diet, and of climate; and those social and moral forces which exercise so great a power on the varying conditions of civilized life; and then say whether it can be expected that we shall be able readily to arrive at grand generalizations on disease. In the great progress which has been made during the past fifty years, we have the strongest possible indication of increased progress in the future. The labors of each generation will correct some errors of the preceding one, and will carry us somewhat nearer to the truth; but the temple of medical science can never be crowned. Each addition to our knowledge will but point out to us fresh fields for labor—new subjects for investigation; and we may rest assured that the demands which will be made on the practitioners of medicine will ever be increasing, as it shall become more apparent how intimately their labors, and the sciences on which medicine depends, are associated with the well-being of mankind.

And there is, I think, a favorable circumstance in connection with our profession at the present time which is likely not only to have a beneficial influence on its actual advance, but with reference to the estimation in which it will be held by the public at large. Resting, as it does, on a basis of scientific observation, and depending for its progress on scientific researches, it will meet with more and more recognition in proportion as it appeals to a public which is more and more scientifically educated; and we now see that physical science is assuming, more and more, its proper position in the education of the young. While I would express a hope that, in the general education of the people, and especially of those who are in the higher walks of life, the cultivation of literature in its widest sense will always maintain a due prominence, I trust that the movement which is now so perceptible, with regard to the teaching of physical science, will continue to meet with that support which I think it so fully deserves; and in connection with this subject I cannot but express the satisfaction which I, and I am sure I may say we all, have felt in seeing rise up, in the various great centres of population in this kingdom, those institutions for higher education which add so much to the teaching power of these centres. The movement is really a comparatively recent one, and we in Liverpool were somewhat backward in it; but a few years ago, some of those who had long felt the want which existed, determined to make a strenuous effort to give to this city what Manchester, Birmingham, and other cities had already provided for themselves. Relying on the liberality of the public of Liverpool, an appeal was made for the foundation of a college in which the higher branches of the arts and sciences should be taught. That appeal was largely responded to, and now I see in our midst a college, with a staff of professors, which I trust is destined to do a work which will reflect honor on itself, and credit on those who founded it. It is true that, as yet, the organization of the institution is not complete, and that a further sum of £50,000 is wanted, in order that the full advantage of affiliation with the new Victoria University may be reaped. But we are sanguine that this amount will soon be forthcoming, and that the position of equality with Owen's College with regard to university degrees will be assured.

The School of Medicine, so long known in connection with the Royal Infirmary, has now become the Medical Faculty of the College.

Since we met in Liverpool, as I have already said, nearly a quarter of a century has elapsed; and by the gaps which time has made in our ranks, and the fact that the Association is now reassembled here, we are reminded, that while individuals pass away, societies and communities may remain. I trust that the time is far distant when our society will show any symptoms of degeneracy or decay; but in its very magnitude and its great prosperity there exists an element of danger. I have, however, the strongest possible conviction that the wisdom of the Association guiding and directing its executive body, which shall be at once the representative and the reflex of the whole constituency, will conduct the society safely through the dangers and difficulties which may beset its path. United, we are all-powerful. Acting in unison, and animated with one feeling for the progress and well-being of our profession, there is no subject in connection with its scientific, its political, or its social aspect which we may not grapple with, and grapple with successfully. As year by year rolls on, we may hope that our numbers will increase, until at length it shall be a very exceptional circumstance in this country for a member of our calling not to belong to the British Medical Association. In concentrating, as we may then be able to do, the whole force of the body medical on any given object, we shall exercise a power which may either compel nature to reveal her innermost secrets, or influence a government in the legislation of the state.

But time warns me that I must bring my remarks to a close. Looking to the results which have been achieved, I feel warranted in saying that, with our present advantages, and working from our present standpoint, we have every reason to believe that the progress of medicine in the future will be marked by more rapid strides than those which have characterized it in the past; and, standing here to-night, I can look forward, with confidence, to the time when a future president of the Association, inaugurating the centenary of its birth, shall speak with triumphant voice, and in glowing language, of the advances which our profession shall have made. He shall tell of improved methods of research, and new instruments of diagnosis. He shall speak of the important generalizations which the collective investigation of disease, carried on for fifty years, has led to. He shall point to the greater facilities with which the differentiation between functional disturbances, and the early symptoms of organic disease may be effected. He shall, perhaps, be able to show how many affections which ultimately lead to great alteration of structure, and eventually to a fatal issue, have their origin in functional disarrangements neglected in their beginnings, and gradually inducing changes which at length become irremediable; and thus he shall show how closely physiology and pathology are connected. He shall, perhaps, be able to point to the establishment of the true pathology of those diseases which from recent investigations appear to be dependent on the presence of micro-organisms, of tuberculosis, and other allied affections, and, as a result of this, he may possibly tell that, by the adoption of a practice analogous to that which has had so marked a result in reference to splenic fever and chicken-cholera, and which has rendered famous the name of Pasteur, an almost complete immunity is enjoyed from those terrible maladies which have hitherto in large measure baffled the skill of the most accomplished physicians.

And, gentlemen, among the many changes which, I venture to think, these revolving years will bring, may we not hope, that, with the higher status as a science which medicine shall have attained, and the higher estimation in which the profession shall be held, will have come a fuller recognition of the claims of its members to some of the higher honors of the State, and perhaps the president of that occasion, or some of those who may listen to his words, may belong to that upper branch of our legislature to which hitherto no practitioner of art

has reached. The votaries of medicine want no other encouragement than that which comes from advancing their own science to stimulate them to the highest exertion for the general weal, but it cannot be doubted that both in the interest of the public, and in reference to the promotion of the health and well-being of the people, the presence of medical men in the House of Lords would strengthen the powers of that House and beneficially influence legislation.

But if the results to which I have alluded, and the advances which I have ventured to foreshadow, are to be realized, if medicine is to be raised from the region of empiricism, and to be placed on a higher scientific level, and if we in this country are to take our part in the researches by which the great problems now awaiting solution are to be determined, then must all unwise legislative restriction on the work of the physiologist and pathologist be withdrawn; then must all measures which fetter the action of the original investigator be removed; and I trust that, by the labors of the society which has been established for the cultivation of medicine by original research, a more enlightened public opinion will be formed, which will aid in bringing about these results.

Medicine must more and more proceed on the lines of exact observation and careful scientific inquiry; and in connection with this it is satisfactory to know that one of our great guilds is about to devote a portion of its means to the encouragement of work such as I have referred to: and I trust that our own society will be able yearly to devote larger sums than at present to a like cause.

And now, gentlemen, in conclusion, permit me, in the name and on behalf of the local members of the Association, to bid you all a cordial welcome to Liverpool. Our Association is now so numerous and so powerful, its meetings offer so many features of interest and attraction, that, wherever they may be appointed to be held we look forward with confidence to large and influential gatherings; but we desire that this meeting shall not only be successful in a scientific and professional point of view, but shall also be rendered interesting and agreeable to all who may honor us with their presence. We cannot show you grand architectural monuments mellowed by age and famous in the annals of history, such as characterize our metropolitan towns; we cannot take you to classic halls like those which give so great a charm to the visits which we pay to our university cities; but we trust that in traversing the different parts of this great centre of commerce, and in visiting the docks which line the shores of the Mersey, you may see something that will interest you; and that when your temporary sojourn among us shall be over, you may feel that, not only have you assisted at a successful anniversary of the British Medical Association, and contributed to the promotion of those objects for which it was founded, but that your visit has been one of satisfaction and of pleasure.

THE CHLORAL HYDRATES.—Mr. Joseph Bemrose, Lecturer on Practical Chemistry in Bishop's College, states that what is usually prescribed as croton chloral is really a butyric chloral. He says: To show clearly the relation existing between the acids—acetic, crotonic and butyric—and their aldehydes and tri-chlor derivatives we may formulate them as follows:

	Acid.	Aldehyde.	Chloral.
Acetic.....	CH_3COOH	CH_3COH	CCl_3COH
Crotonic....	$\text{CH}_3(\text{CH}_2)\text{COOH}$	$\text{CH}_3(\text{CH})\text{COH}$	$\text{CCl}_3(\text{CH})\text{COH}$
Butyric.....	$\text{CH}_3(\text{CH}_2)_2\text{COOH}$	$\text{CH}_3(\text{CH}_2)\text{COH}$	$\text{CCl}_3\text{CH}_2\text{COH}$

The hydrates of the first, $\text{CCl}_3\text{C}(\text{OH})_2\text{H}$, and of the third, $\text{CCl}_3(\text{CH}_2)_2\text{C}(\text{OH})_2\text{H}$, of these chlorals only are in use in medical practice; and although this has been pointed out many times since 1876 we still find the latter more frequently prescribed by the wrong name, croton chloral hydrate, than by the right one butyric (or butyl) chloral hydrate.—*Canada Medical Record*, February, 1883.

ON THE AUTONOMOUS LIFE OF THE SPECIFIC INFECTIONS.

BEING THE ADDRESS IN PATHOLOGY DELIVERED BEFORE THE BRITISH MEDICAL ASSOCIATION AT LIVERPOOL, AUGUST 3, 1883,

By CHARLES CREIGHTON, M.D., M.A.

LONDON, ENGLAND.

MR. PRESIDENT AND GENTLEMEN: I have unusually good reasons for prefacing my address with an apology. I cannot claim to speak from the fulness of experience which has given so much value and distinction to the addresses that have been delivered before the Association, and I have a subject assigned to me which demands experience and a mature judgment in no ordinary degree. Pathology is a growing science, its aspects are constantly changing, a single year's work brings us a multitude of new and often puzzling facts; and although the issues are of the most momentous kind, not even the wisest and most judicial minds in the profession can always see their way to a clear and definite opinion.

But, amidst all this uncertainty, there is one central and guiding principle in the doctrine of disease which we may hold fast to. It is the physiological principle, or the idea that diseased states of the body are but modifications of healthy states, deviations from the beaten track, perturbations of the normal life, shortcomings of the physiological standard. Thus, even in so formidable a malady as diabetes, we are still within sight of the line of health; there may be a physiological glycosuria; and that fact, as Dr. Bence Jones says, proves to us that the disease is only a little way distant from health. "Here, as elsewhere," says that eminent chemist and pathologist, "there is no definite limit where health ends and disease begins." To find the proper physiological analogies for diseased processes is the task of modern pathology; and I do not think that there is, in the whole range of science, any better kind of intellectual exercise than to expose the working of the ordinary laws of structure and function under the mask of disease. The physiological idea is, indeed, the hope and inspiration of pathological science, as it is also of medical practice. But there is no reason why I should attempt to say again what has so often been well said before. Members of the Association who heard Professor Michael Foster, at the Cambridge meeting, discourse on the "Relations of Physiology to Pathology," will not have forgotten how he proved that the difference between these two sciences was merely a superficial difference, whether as regarded method or subject matter. We shall, most of us, also recall Professor Huxley's lucid exposition before the International Medical Congress, of the "Connection of the Biological Sciences with Medicine," wherein he showed that pathology was that branch of biology which concerned itself with perturbations of the normal life.

That view of pathology is one that we all share; and as I have endeavored, according to my opportunities, to work out physiological analogies of disease in particular instances, I shall not be suspected of any want of sympathy with the general principle. But I am none the less confronted with the difficulty that a great deal of pathology appears to be quite different in kind from any physiology known to us. What are the physiological analogies of the infective and constitutional diseases, and how large a part of pathology do the diseases of that class stand for?

There is, I believe, a serious difficulty here, and a difficulty that made itself felt in the very first system of physiological medicine that was given to the world. Broussais was the author of the first attempt at a physiological scheme of disease; and it was only a year or two ago that Professor Charcot was claiming for his brilliant countryman the credit of having broken down the dualism of health and disease, and of having eradicated that old and pernicious habit of regarding disease as a separate entity. But Professor Charcot said no-

thing of the rock on which Broussais is generally accounted to have made shipwreck. The author of the first physiological medicine was thorough-going, and it was because he endeavored to be comprehensive and consistent that he failed. He left out no great disease from his physiological scheme, not even typhus nor Asiatic cholera; they were all perturbations of the normal life, and a good many of them were forms of gastro-enteritis. Professor Charcot may be right in claiming the physiological medicine of Broussais as the example for all subsequent times; but it is quite certain that it served also as a warning to those who next took the physiological medicine in hand. They were careful to lighten the ship by throwing overboard Asiatic cholera, typhus fever, and, in fact, the whole of the acute and chronic infections. Just about the time when the thorough-going system of Broussais had provoked the inevitable reaction, Professor Henle had made his suggestion about minute parasitic organisms being the causes of the specific infective diseases; and it is curious to read, at a distance of forty years, in the first volume of the German *Archives of Physiological Medicine* (p. 88), how Griesinger, one of its sponsors, promptly availed himself of the parasitic hypothesis of Henle in order to account for all those diseases which had been prudently omitted from the physiological programme.

But I venture to say that, when we congratulate ourselves upon the physiological basis of pathology, we do not always reflect how much of disease is thus excluded from the class of disturbed physiological processes, and how small a fraction remains to fill the physiological categories. There are several passages in Sydenham's works in which he gives his estimate of the proportion that the species of disease—the *morbi typo induti*—bear to the rest; he estimates diseases of a specific type at two-thirds of the whole; and it will be admitted, I think, when we look abroad as well as at home, and we read history as well as contemporary records, that this estimate shows his fairness of mind and his sense of proportion.

The serious difficulty, then, which I spoke of—the difficulty that must have been present to the mind of Broussais, and must occur more or less to every one—is that a physiological medicine, which leaves out the larger and more formidable half of disease, is hardly worthy of the name. The doctrine that morbid processes are after all merely perturbations of normal processes, or, as Hunter said, "a perversion of the natural actions of the animal economy," is the great principle of scientific pathology; but we shall have to speak less enthusiastically of it, if it should appear that it has no place for the long list of infective diseases—for plague, for cholera, for yellow fever, for typhus, for small-pox, for leprosy, for syphilis, for cancer, for consumption. If the physiological idea is to be good for anything, it ought to be good for those; for they are the real difficulties of pathological science, and the real *opprobria* of the medical art.

I am sanguine enough to believe that the physiological doctrine will one day be shown to be as large in its application as it is rational and hopeful in its spirit. It is for that reason that I have decided to use this public opportunity that has come to me—and come to me most unexpectedly, and, I feel, most undeservedly—in order to speak of certain aspects of the specific infections, which are perhaps not the aspects most commonly brought before us at present. One would wish to think of these diseases, strange and terrible though they be, as still joined in continuity with the common disorders of structure and function; and I am accustomed to express for myself this connection by a formula, which has no other value than belongs to a mode of thought or a form of words, but may still serve as a convenient or empirical standing ground for those who seek to observe a certain unity and sequence in their study of disease.

I shall endeavor, then, to discover some relation be-

tween common aberrations of structure and function and the specific infections, or a relation between disordered states of the body and the self-existent species of disease; and I shall make this attempt with two or three representative instances. It will be convenient to begin with cancer, for the reason that the suggestions that I have to make arise most naturally out of the study of cancer.

Cancer is an infection, although its infective power does not extend, except in heredity, beyond the individual body in which the disease takes its rise. I do not forget that some pathologists consider cancer to be no more than an overgrowth of epithelium. But we shall find it difficult to explain to a patient with cancer that he is suffering merely from an overgrowth of his epithelium. All the world knows what cancer is, and no microscopic analysis will ever persuade men that cancer is anything but the devouring thing, the implacable enemy that the common eye sees it to be. What the microscope does show us, is that a cancerous tumor has not always been cancerous. If we take any of the common seats of cancer—the stomach, or the uterus, or the breast—we shall find that the disease may be traced back to a point at which it comes within the category of structural and functional irregularities. I say structural and functional, because it seems to me that if we attend only to the structural features of the disorder, as some of our German colleagues are content to do, we are likely to miss the central idea of the deviation from the normal. In the favorite seats of cancer, the secretory function is not always or altogether what we often take secretion to be. Under certain circumstances, solid products, or cells, form part of the secretion, and those cells do not always get carried off, as the cells do in an ordinary catarrh, by discharge from the surface, or by way of the lymphatic drainage, but they may stagnate and accumulate in the deeper textures of the organ or part. So far, there is nothing in the morbid process for which we may not find close physiological analogies. In some of the secretions of the invertebrata, and even in certain glands of the higher animals, the secretion retains its solid or cellular character for a considerable time. Again, the heaping up of the solid or by-products of secretion, in the spaces of the underlying connective tissue, is found to occur in the breast as a perfectly natural incident.

Still further, the free space of a gland may become filled with cast-off epithelial cells; or the epithelial lining may be raised into wart-like growths. Even a whole gland, like the breast, or a whole lobe of the gland, may be uniformly affected in the way of overgrowth, producing an adenomatous condition, or the condition of simple glandular tumor. There is nothing cancerous in all this; we are still within sight of the line of health. The cancerous element comes in usually after a particular time of life, and it consists in the implication of other tissues than the glandular or secreting structure, whose irregularities were the exciting cause. Epithelial cells that have not been used for secretion can become mischievous as infecting cells, and if we now examine the region of disease, we shall find the marvellous spectacle of an epithelial kind of structure springing from the tissues around, where there is no epithelium naturally; a little later, the same epithelial pattern is, as it were, carved out of the parenchyma of lymphatic glands, or of the liver, or in the deeper layers of the skin, or even in still more unexpected places. The pattern of this widely distributed structure is always the same in a given case, and there is always something in it which reminds us of the primary seat of glandular disturbance. An intelligible disorder of structure and function, not without its close analogies in physiology, has acquired a kind of individuality or independence, and a power to reproduce itself throughout the body; or, in other words, it has become a ravaging cancer.

I shall not delay here to go into the particulars of this extraordinary process, or to enter upon controversial

matters. I take cancer as a striking instance of a disease which may be traced along the track of physiological perturbations for a certain distance, after which it becomes what all the world knows it to be—a semi-independent life, an *imperium in imperio*, a power inseparable from the general life of the body, compatible even with blooming health for a time, but in the end sure to gain the mastery.

In taking a full and fair view of cancer, of its physiological beginnings, and its ultra-physiological course, we cannot but admit that there is some truth in that hard saying of Paracelsus: "In such a disease, a man is himself and another, he has two bodies at one time, enclosed the one in the other, and yet he is one man." This kind of Platonic mysticism is not what one would choose to import into exact science. But we are bound by a regard for facts; and I do not see how the facts of cancer, whether they be microscopic or clinical, can be done justice to unless we admit that a state of the body may be raised to the power and dignity of a life of semi-independence. I purpose speaking, in the sequel, of this semi-independence under the name of autonomy; and I shall endeavor to show, in the case of two or three other representative infective diseases, how a perturbation of the physiological life has acquired its autonomy, or what the pre-autonomous stage of those infections may have been. This doctrine of acquired autonomy and the pre-autonomous stage is the formula in terms of which I would express the relation between ordinary perturbations of structure and function and the specific infections, the relation between disordered states of the body and the self-existent species of disease.

If cancer has always been the great popular instance of a disease enjoying a kind of life of its own within the body, consumption hardly yields to it in its relentlessness, and it far exceeds it in its prevalence. Is it possible, in the case of consumption, to show that a wasting infection has arisen out of common disturbances of the physiological life? Before so critical an audience, I shall not have the hardihood to speak of consumption in general—of the disease about which so great masters in pathology as Laennec and Virchow have differed widely. But there is a form of tubercle, the bovine form, in which the facts are much less ambiguous, and much easier to deal with, and, as it happens, more familiar to myself; and for bovine tubercle, or, as it is sometimes called, the pearl disease, I shall venture to inquire whether the small beginnings of it may not be found in a certain kind of disturbance of ruminant nutrition, just as we find the pre-cancerous stage of cancer in certain irregularities of the apparatus and process of secretion. Those beginnings would correspond to what I have called the pre-autonomous stage; while the autonomous life of the disease, as a semi-independent thing, would be shown in its infectiveness.

Bovine tubercle is a more complete example of infection than cancer. It is a constitutional disease, pervading the whole body; it is likely to end in wasting and cachexia; it is very liable to be inherited by the offspring; it can be given to other animals, by inoculation or by feeding, in experiments, and probably also by accident; and there are recorded cases, in veterinary practice, which lead us to think that it hangs about a stall, or spreads from stall to stall by volatile contagion. There is, in fact, no disease, in human or veterinary pathology, that shows a more complete autonomy; it is constitutional, hereditary, infective, and contagious.

The pearl disease is peculiarly a ruminant malady, and it is curiously limited within the ruminant order itself. It does not occur in the sheep, nor, as far as we know, in the deer; and by far the larger number of cases are found in the domesticated bovine species, in which it is, indeed, much too common. I have been on the outlook for specimens of it among the animals that die in the Zoological Gardens in London, and my experience hitherto has been curious and suggestive. I have

hitherto found the peculiar anatomical characters of this form of tubercle in only three species: the eland, a large South African antelope, like a cow; the nil-gau, a large Indian antelope, whose name means "the blue cow;" and the prong-horned antelope, from America, another of those half-way animals between the bovines and the antelopes, which the late Mr. Forbes, the prospector at the Zoological Gardens, took much interest in as a transition species. It is certainly a remarkable thing that those antelopes, which resemble the bovines so closely in zoological characters, should resemble them also in their liability, under confinement, to a distinctive kind of new formation. This kind of tubercle is not only an affair of the ruminant order, but it is an affair of a small group of ruminants, mostly belonging to one genus.

What, then, are the distinctive anatomical characters of this distinctively ruminant disease? The morbid anatomy of bovine tuberculosis has been written with as little reference to theory or preconceived opinion as could be wished. It has been, in great part, observed by those whose business lies with cattle; and the popular names of the disease in all countries will show us how it has presented itself to the common observer. The various names show that it is primarily an affection of the serous membranes; the Germans have called it the "pearl disease," from the rounded whitish nodules attached to the abdominal and thoracic surfaces; the French have named it "pommelière," from a fancied resemblance of the nodules to clusters of potatoes; in England, it has been called "the grapes;" and, in Scotland, "angle-berries." I am merely repeating the language of all authorities, including Professor Virchow, when I say that the disease is primarily one of the serous membranes—a growth of multiple nodules, usually small and flattened, often suspended by a stalk, and sometimes as large as a cherry or an apple. These are the beginnings of the disease; but it extends from the serous membranes, by infection, to the lymphatic glands, which become changed into the same mortar-like substance that is found in the degenerated nodules. The lungs, also, are very apt to get infected, as they so often do with new formations of a sarcomatous nature; and the infection may, in the end, reach most of the organs, as well as the bones and joints, causing the animal to die of general cachexia and wasting.

Such is the usual sequence of events where the disease is originally acquired; but in the cases of inheritance—and these are now estimated at more than one-half—there may be some departure from this order; in them, the formations in the lymphatic glands, lungs, and other viscera, may be more conspicuous than the serous-membrane nodules; but even in the inherited disease, the pleural or peritoneal surfaces will usually show characteristic traces of the primary new formation. Some allowance must be made for certain modifications in the order and distribution of the disease, when it is communicated directly to the offspring by a sire or dam which had acquired it; and it is all the more necessary to be clear on this point, since, at the present day, the hereditary taint would seem to be so widely distributed throughout the bovine stock as to obscure somewhat the original characters of the disease. In what I have to say, I must speak of the disease as it is primarily acquired, and as it is described in the earliest writings, and by its popular names.

It starts, then, as a multiple nodular condition of the abdominal and thoracic serous surfaces, it acquires the character of a constitutional disease, it goes all through the body, it passes directly to the offspring, it may be inoculated upon healthy animals or communicated to them by feeding, and it is not improbable that it passes by volatile contagion. The infectiveness within the original body, and the faculty of passing to other animals, is what I would call its autonomous life, and I would look for its pre-autonomous stage in the peculiar groups

of multiple nodules on the serous surfaces. What then is the origin of these nodules, in what relation do they stand to any known disorders of ruminant nutrition, or, rather, of the nutrition of those ruminants that are closely confined, artificially fed, and over-milked?

I am not aware that the suggestion which I have to make has occurred to any one before, and I put it forward, therefore, with some diffidence. This suggestion arises out of a consideration of the forms and favorite seats of the nodules, and of their structure, and degenerations. One cannot help observing that these multiple nodules are especially apt to grow in the seats of fat-formation, and to assume the external form of deposits of fat, either the stalked and pendulous form, or the flattened form of confluent lobules or patches. Now the bovines are somewhat peculiar in the way in which they lay on fat. They have not so much of subcutaneous fat as the sheep or the pig, but they are very apt to have internal formations of adipose tissue, sometimes in situations where one would imagine that it could serve none of the ordinary purposes of fat. Besides the common deposits of fat about the abdominal organs and in the thorax, there may be lumpy masses of it even on the pleura covering the ribs, and on the diaphragm; and, in highly fed animals it is not unusual to find a lobulated layer of the same tissue all over the surface of the spleen, and even on the surface of the liver. It can hardly escape us that those serous surfaces which are invaded in the course of this excessive fat-forming habit, are just the localities where the pearl nodules are found. There is, indeed, one rather important exception to this rule, namely, the borders and surfaces of the lungs. I cannot say whether a border of fat ever occurs round the margins of the lungs in cattle, as it occurs round the spleen and liver, or under the pulmonary pleura, as it is found under the costal pleura; but, if that should be the case, the analogy with the pearl disease would be complete, so far as situation goes; otherwise, we must explain the nodules of the pulmonary pleura on the hypothesis of secondary infection. As regards form, the resemblance between the physiological and the pathological formations is most striking; in both cases we may find either a finely lobulated stratum of translucent tissue, or coarser lumpy masses, or pendulous nodules.

But, after all, the diseased nodules of the serous membranes are not fat, or, at all events, they are not composed of adipose tissue throughout most of their extent. They are not multiple lipomata; but it would be strictly correct to describe them as multiple fibromata, or sarcomata, with a deficient blood-supply, or rather as a multiple tumor-formation, containing a mixture of those two kinds of tissue, growing in the seats of fat-formation, and assuming the lobulated, or lumpy, or pendulous forms of the sub-serous fat.

I do not think that I have gone beyond the facts in this statement of the naked-eye characters of the primary new growths to which the bovines are so liable, and I cannot help thinking that there must be some connection between them and vicissitudes in the nutrition of those animals as manifested in that tissue which would be most affected in nutrition, namely, the fat-tissue. The facts may be explained in two ways, both of which may be applicable, although I would regard one of them as more probable than the other. Either the formations on the serous membranes are atrophied or degenerate masses of fat in which the blood-supply has failed to a great extent, or they are radically new growths which have sprung up in the old lines of fat-formation, or where fat may once have been. The description in a veterinary text-book of retrogressive clauses in the multiple lipomata of the serous membranes, reads very much like a description of some of the bovine tubercles that we meet with; the oily contents of the fat-cells disappear, the connective tissue hardens and thickens, calcareous matter is deposited, and a mortar-like substance takes the place of what once was fat. But there is another

and perhaps better way of accounting for the fact that the morbid growths are found in some of the favorite seats of the internal fat, and in its peculiar shapes. It is a well-known zoological characteristic of the bovines that their fat is naturally apt to come and go from time to time, in the wild state according to the periodicity of the seasons, and in the domesticated state according to a multitude of artificial practices in the management of dairy and farm stock. Nothing can be more artificial, for example, than the conditions which cows in town dairies are subjected to: the close confinement, the unnatural feeding, and the excessive milking. It is quite conceivable that an animal, under those circumstances, and more especially when it is growing old, would depart from its natural fat-forming habit, and put on, instead, an embryonic kind of tissue, which is neither fat nor anything else of a physiological kind, although it occupies the old seats of adipose tissue, runs into the familiar mould, as it were, and grows to the old pattern.

Whether we take the one explanation or the other, or the two together, there is, I think, a pretty strong chain of evidence that bovine tubercle begins as a disorder of nutrition. It is oftenest acquired by animals that are farthest removed from their natural conditions—by cows imprisoned in town dairies; and the disease that those animals are so peculiarly liable to begins as a kind of multiple morbid growth, which occupies the very seats of the internal fat, and runs into its very shapes. Now, the abdominal and thoracic fat is precisely the tissue that might be expected to show the effects of malnutrition in the way of structural changes. The tubercles are simply collections of embryonic tissue in which the formation of blood-vessels has been inadequate, and in which degeneration has inevitably followed; and any one who has studied the development of fat will readily admit that the same embryonic cells growing in the particular localities might have become fat-cells if the blood-supply had been sufficient.

Whether I have indicated truly or not the circumstances in which we should seek for the beginnings of this peculiar kind of new growth, I am confident, at least, that we must look for these beginnings in some physiological disorder or other within the small group of ruminants, and not elsewhere. Disordered nutrition appears to me to be able to account for this kind of multiple tumor disease, just as I believe that disordered secretion can account for the beginnings of cancer. Disordered nutrition shows itself in various ways within the body; but there is only one tissue that it specially affects, and that is the adipose tissue, just as the glandular tissue is the proper seat of secretory disturbances. In the one case as in the other, the disorder of function finds a structural expression; it acquires length, breadth, and thickness; or, in other words, it results in a tumor. The functional disease thus acquires the degree of individuality which may be ascribed to a tumor, and that must be the beginning of its life of semi-independence within the body. In both cases, the pre-autonomous stage is a common disorder of structure and function—of secretion in the one case, and of nutrition in the other; and each goes on to acquire the mysterious power of infection. But they become autonomous in different ways, or under different circumstances. I have already spoken briefly of cancerous infectiveness, and I have elsewhere endeavored to trace the connection between it and the antecedent glandular disturbances. In bovine tubercle, I should ascribe the infectiveness to the *multiplicity* of the primary nodules, and to the fact of their being seated on the serous membranes, which are so fundamental a part of the lymphatic system. Multiple tumors of the serous membranes are favorably situated for infecting the lymphatic glands, and the infection of the lymphatic glands is only the beginning of an autonomous career. Professor Virchow has shown, in his great work on morbid growths, how the lobules of abdominal fat may become multiple stalked lipomata, each lobule becoming a

kind of individual tumor and growing as such; and he adds the following remarkable words: "There is no doubt that this kind of multiplicity does not differ altogether from what we find in malignant tumors or in an infective dyscrasia;" and if that can be said of multiple lipomata still retaining the proper structure and nutrition of fat, it can be said, with even greater truth, of those multiple growths of the abdominal and thoracic surfaces which we have good reason for taking to be rather the degenerations or substitutes of the fat.

There is one other point to be noted in connection with bovine tubercle. It may or may not be primarily due, as I have supposed, to an error of nutrition in the abdominal and thoracic deposits of fat, but its morphological characters are certainly peculiar, and they belong, in a sense, to the bovine organization. If I may so speak, it has sprung out of bovine soil, and the marks of its bovine origin never quite leave it, even when it is set up in the bodies of animals widely removed from the ruminants. A mere condition or state of the ruminant body can be abstracted, as it were, from all other ruminant conditions, and made to live in another body; and that is an extreme instance of what is meant by the autonomous life of the specific infections, or of the semi-independent existence of the species of disease.

Having presented cancer, and one of the varieties of tubercle, in this light, I shall next inquire whether the formula of an acquired autonomy may not be applied to a third great disease, representative of another class of infections, I mean small-pox. Small-pox may be looked at from more than one point of view without losing sight of its main features. Our great English dermatologist, Willan, looked upon small-pox as a skin disease; but Willan was also one of the first to investigate the history of small-pox epidemics throughout the world, and he was not likely, therefore, to underrate its importance as a pestilence. Hebra also ranks small-pox among the cutaneous disorders, and the authorities of the Allgemeine Krankenhaus at Vienna have given practical effect to Hebra's doctrine so far as to place the small-pox wards under the department for diseases of the skin; and I can testify, from an experience of the Vienna small-pox wards, that the disease does not lose any of its contagious power by being classified among skin diseases. An experience gained under those circumstances is apt to make an impression, and, from that time, I have never quite been able to think of small-pox except as an ill-smelling condition of the human skin which one person may impart to another. It is a skin disease which has been reproduced with the greatest accuracy and fidelity in millions of copies for hundreds of years, and the extraordinary closeness of the mimicry has given rise to the opinion that the disease is really the uniform effect of some unknown poison. But the anatomical structure and evolution of the pock is too elaborate to be the simple and direct effect of an intrinsic poison; it is not like a flea-bite or like the nettle-rash which comes out in some peculiarly constituted persons after eating shell-fish, or, as I have known, even from eating a single wholesome strawberry. The pock is a complicated affair, and there is a history written in it, a history of characters acquired bit by bit, as in the evolution of living things, a history which has been transacted within the body; and the stages of this history are run through with more or less completeness in every case of the communicated disease. The papules had developed fluid in their summits, they had grown in a peculiar way to the breadth, the original centre had become a distinct depression, and in the course of this evolution certain partitions had been formed in the interior of the pock. Further, the pock is more deeply rooted in the skin than most skin diseases known to us; for its base goes down to the vascular layer of the corium, and, when it scabs it leaves a considerable defect of substance (more particularly in those localities such as the face, where the vascular layer of the corium is well-developed), a peculi-

arity among skin diseases which can hardly be matched unless it be in some of the tropical forms of "impetigo." This skin disease is ushered in by much constitutional disturbance or fever; and, as in some other skin diseases which are not contagious, the fever abates when the eruption has come out, and the subsequent constitutional disturbance is exactly in proportion to the number of the pocks.

The remarkable thing is that all this complex of anatomical structure, of stages of evolution, and of characteristic fever, should have preserved its unity and individuality through so many transmissions, in all sorts and conditions of men, and in all parts of the world. The disease possesses what I would call autonomy in a high degree, and, from that point of view, it becomes a matter of no ordinary interest to inquire into its pre-autonomous history.

Professor Hirsch, in his "Handbook of Geographical and Historical Pathology" (a work which we are soon to have in an English dress), concludes an elaborate review of the historical evidence about small-pox, with the opinion that we have to go to tropical countries, to Hindostan and to the interior of Africa, for its original seats, and to go back to a remote antiquity to find the beginnings of it. Lichtenstein, one of the early explorers of Africa from the southern end, found small-pox to be prevalent wherever he penetrated to, and he found it among tribes who professed to have got it from nations still farther from the sea. According to Pruner, the disease is peculiarly an African disease. We may take it, therefore, that small-pox was originally a disease of the black skin, and it is in keeping with that historical and geographical induction to find that the black-skinned races are by far the most susceptible of the disease even nowadays, when it is set up only by contagion.

It is impossible to speculate to any purpose on the rise and development of small-pox out of some common and frequent disorder of the black skin under such influences as tropical heat and moisture, or under the peculiar conditions which obtain among the swarming populations of tropical countries. One naturally thinks of a complex form of "febrile lichen," a skin disease which Dr. George Gregory admits that he could not always diagnose from small-pox; and if we imagine a widely prevalent kind of febrile lichen to follow somewhat the same development that Willan describes in a remarkable case of lichen agrius, we should have a not very remote analogy for what I should call the pre-autonomous stage of small-pox, both in the structural characters and in the constitutional fever. We are, at least, justified in thinking of some form of tropical skin disease, widely spread within a certain zone, very apt to recur in the individual, and with each recurrence to become more inveterate and to develop a more complex structure. Given a number of people suffering from such a cutaneous disorder at one time, and some great migration or invasion, and we shall probably have the circumstances under which the skin disease would become communicable, would pass by contagion to the skins of those who had never incurred the disease by natural causes, and pass all the more easily to them if they belonged to an entirely different race, or presented the ordinary contrasts of civilization and barbarism, of white skin and black.

I do not say that it is an easy thing to construct the circumstances under which this disease of the black skin acquired, what I would call, its autonomy. It was probably a gradual process; its semi-independence must have been hardly won and slowly consolidated, until, at length, it was ready to start on its devastating campaigns. Small-pox has been a disease on so stupendous a scale that it must seem to be mere hardihood to speak of it as a condition of the skin, originally acquired in the tropics, which has been passed on from one body to another. But, even if history and geographical distribution had told us nothing, the loathsomeness, the peculiar odor, and the no less peculiar scars of small-pox, might of

themselves suggest another skin than ours; and I have seen too many instances of the minute mimicry that goes with every infection to feel any surprise that a disease which is native under a tropical sun should impress upon its victims in every country something even of the primary ethnological characters.

And now let us compare the autonomous disease, as we know it, with the original skin disease out of which it must have grown. The contagious small-pox is distinguished by what Sir Thomas Watson calls "the very curious fact" that it generally occurs but once in a person's life. "In this," says Watson, "the contagious disease offers a remarkable contrast to inflammations, which, having happened once, are, for that very reason, more apt to happen again;" and he goes on to show the impropriety of ranking small-pox under the head of cutaneous diseases; it would "more rightly be called a blood disease." But there need be no antagonism between the view of small-pox as a cutaneous disease, and the view of it as an infection. This formula of an acquired autonomy, and of a pre-autonomous stage, which I have been recommending as a sort of nostrum for our intellectual difficulties, appears to me to be a means of reconciling those antagonistic opinions which have arisen, not so much in connection with small-pox, as in the controversies about some other infective diseases, which are supposed still to develop *de novo* from time to time. Small-pox, in its pre-autonomous stage, would be precisely that kind of skin disease which, having happened once, is, for that very reason, more apt to happen again; it would recur in the same spots, as in the early stages of leprosy, and it would become more rooted and more inveterate each time it came back. The inveteracy of this morbid condition of the skin, due in part to neglect, would be its first step toward acquiring that remarkable power of semi-independence within the body, which I have been endeavoring to illustrate under the name of autonomy; it is this acquired power which enables it to pass to another person's skin as an individual state of the body, which can be, as it were, abstracted; and its individuality is proved by the best of all tests of what constitutes an individual—the test of parentage; for the skin disease that springs up in the contaminated body is exactly like the skin disease which must have been originally acquired. But the infected or impregnated body runs through all the stages of the malady—papule, vesicle, pustule, scabbing, and scarring—in rapid succession in two or three weeks, and it is thenceforward done with that particular form of skin disease for ever. The autonomous form of the disease is a brief abstract and chronicle of its whole protracted development or evolution; it sums up the past, and just as it sums up the past, so it anticipates the future.

Small-pox appears, then, to be a clear case of a morbid condition of the body, namely, a cutaneous condition, which has been enabled to lead a kind of independent life. But small-pox is one of those diseases that always pass directly from one body to another, and the direct succession of cases does not appear ever to have been broken. There is, however, another large class of infections, corresponding to Pettenkofer's division of the exogenous contagia, which are not only able to subsist for long periods outside the human body, but which even require a certain amount of external putrefaction in order to make them potent. Cholera is one great example of a disease of the exogenous group, and yellow fever is another; and I shall ask your attention for a few minutes to some facts relating to the latter disease; for here, at least, it must seem as if we had got quite away from common disorders of structure or function, and into an absolutely separate region of disease, where the physiological principle does not serve us.

Yellow fever is one of those maladies in which historical and geographical facts are of even greater importance than microscopic or chemical, and hardly less important than clinical; and, as I have been lately occupied in

turning into English the German sentences of Professor Hirsch's treatise on "Geographical and Historical Pathology," I have had occasion to reflect upon the more salient facts in the history and geography of yellow fever. The first point that strikes one is, that it appeared in the seventeenth century as a new disease; for more than a century after the Spanish conquest of America, and for many years after the first English and French colonization in the West, there was no yellow fever, and, when it did come to Guadaloupe and Barbadoes, it was recognized as something quite different from the ever-present malarial fever. The next point is, that there is something quite peculiar in its geographical distribution. At the present day, we are apt to think of yellow fever as the fever of the Gulf of Mexico and Brazil; but it had been the scourge of Philadelphia, and even of New England, for many years before it broke out in New Orleans at all (1796); and its first appearance at Rio was in 1849. In reading Bancroft's treatise on this disease, published in 1811, it is curious to notice how much yellow fever has shifted its ground; it has always remained true to certain shipping-places in the West Indies, but the other great centres in Bancroft's time have absolutely ceased to be the seats of yellow fever; and some of the places that are among the worst seats of the fever now are not even mentioned in Bancroft's pages. In fact, it is not latitude and longitude that explains the peculiar distribution of the disease. There is only one thing that covers its history and its geography and the remarkable changes in its distribution, and that is the slave-trade. Disregarding its occasional and widely ranging excursions, and confining the attention to the localities where it is or has been, at one time or another, endemic or repeatedly epidemic, these are found to be the creeks and wharves and low shipping-quarters of the ports of debarkation of the slave-trade, together with a few much less endemic, but not less significant spots in Spain and on the west coast of Africa—the places to which vessels engaged in the contraband slave-trade had gone on their return voyage. The single exception to this curious rule is Peru; but Peru is hardly an exception, when we bear in mind the many points of resemblance between its coolie trade across the Pacific and the old African slave-trade.

It was an inquiry into the disastrous outbreak at Barcelona in 1821, in which five thousand persons died, that gave the first clue to the connection between yellow fever and the slave-trade. The circumstances were investigated by Dr. Audouard, for the French government, and the same physician was sent again in 1823 to inquire into a more limited epidemic at a small port in Biscay. The facts were very much the same in the two outbreaks; ship-carpenters, engaged in repairing vessels that had arrived some time before from the West Indies, were seized with a prostrating illness, which they attributed to putrid emanations from the bilge-water, and they became the first victims of an epidemic which proved to be yellow fever.

Dr. Audouard found that the vessel which started the infection in the 1823 epidemic was a slaver; and, on recalling the facts of the Barcelona outbreak two years before, he found that the two vessels chiefly concerned in it were also slavers, in proof of which, he said, they might still be seen with the irons for securing the slaves fixed in the planking of their holds. It was ascertained also that one of them had had an extraordinary amount of dysenteric sickness and mortality among her human cargo on the previous voyage. He calculated that about sixty Spanish vessels had been engaged in this contraband trade in 1820, that they had taken out about fifteen thousand slaves from Africa to the West Indies, and had returned to Spain with merchandise before going down to the African coast for their next cargoes. This was, in fact, the time of the irregular slave-trade, when the vessels were not adapted for it, and the crowding and sickness on board was at its worst; and this period corresponds to the remarkable outburst of yellow fever, both in

America and Spain and on the west coast of Africa, from about 1790 to 1820.

It is a perfectly well-known fact, admitted equally by Lind and Bancroft, that the slaves on board a slave-ship did not suffer from yellow fever, although they suffered much from dysentery and from what used to be called the "horrors of the middle passage;" so that a slave-ship would arrive at her destination with no contagious fever on board, but saturated with the filth of her human cargo. The facts discovered by Dr. Audouard in two Spanish outbreaks suggested to him a general theory of yellow fever; it was a peculiar form of typhus due to emanations from the putrid dysenteric discharges of the negro, and the fever owed its well-marked specific type to the fact that the matters which excited it could be traced to the negro body. There was something, he said, quite peculiar in the negro's constitution, and it was not surprising that the discharges from his sick body should be able, when fermented, to produce in others a typhus fever of a peculiar type.

Dr. Audouard's papers were communicated to the French Royal Academy of Sciences, and accepted for publication. The Academy, however, did not adopt his opinions, and they pointed out, after the manner of academies, that his facts related to only three slave-ships and to only two outbreaks. But the author had shown that a great part of the West Indian trade with Spain was carried on by ships engaged in the contraband slave-trade, and that the same circumstances which led to the epidemics investigated by himself must have arisen often at all the Spanish ports where yellow fever was an almost annual occurrence. Not only so, but the whole history and geography of yellow fever in America was on his side; seaports where cargoes of slaves had been landed year after year had presumably become saturated with the peculiar filth of the trade, and it is just the landing-places and shipping-quarters of those ports that are the foci of infection. In some of them, such as Vera Cruz, the poison seems to have become peculiarly fixed in the soil, so as to defy all attempts at getting rid of it. But in the great cities on the Atlantic seaboard of the United States, the fever was practically eradicated soon after the importation of negroes ceased. During the sixteen years after that date (1808), yellow fever appeared only seven times in the different ports of the Union, whereas in the sixteen years preceding the abolition of the traffic it had broken out fifty-eight times.

In the Spanish seaports also, the great epidemics of yellow fever are an almost forgotten tradition. But in Brazil they are of recent date, the first of them as recently as 1849, and Brazil was then and had been for some time the great market for the African slaves, when the ports of other countries except Cuba were closed to them.

A still more unlooked-for confirmation of Dr. Audouard's theory may be discovered in the establishment of yellow fever in the seaports of Peru within quite recent times; the first outbreak having been at Callao and Lima in 1853. An account of it was sent from Lima to the *Edinburgh Medical Journal* by Dr. Archibald Smith, who says: "The first cases of the Lima fever were vulgarly attributed to the excessively crowded shiploads landed at Callao of poor and sickly Chinese, who were ill-fed, ill clothed, and badly cared for on the voyage from their native country. But," he adds, "I, as a practitioner, could not trace any symptoms of this fever to them." But Dr. Smith's objection to the popular explanation of the yellow fever in Peru is precisely the strongest argument in favor of it; the Chinese, like the negroes, did not suffer from yellow fever, and they are said, indeed, never to take it on shore; but they suffered from those dysenteric and other non-contagious ailments which were the antecedents of yellow fever. The disease, since that time, has appeared at various other ports on the Peruvian coast; its outbreak at one of them, in 1868, was so sudden that the populace attributed it to an earthquake; but a communication sent to the French

Foreign Office more reasonably connects it with the Chinese immigration, which, as the report says, has profoundly changed the sanitary condition of the whole Peruvian coast.

But there is another argument for Dr. Audouard's theory, which he makes hardly any use of. It is the immunity of the negro from yellow fever, notwithstanding his great liability to cholera and the common forms of typhus, including ship-typhus. This immunity is perhaps not so striking now, when the negro blood is less pure, but all the earlier authors were much impressed by it. Thus, Doughty, who saw much of yellow fever in Jamaica at the beginning of the century, says: "In the natives of Africa the constitution appeared to me as secure against yellow fever as a person who has had the small-pox"—and he might have said the yellow fever itself—"is against its recurrence." Fenner, a more recent authority in New Orleans, says: "It is a well-established fact that there is something in the negro constitution that affords him a protection against the worst effects of yellow fever, but what it is I am unable to say." Mr. Clarke, the author of a paper on the "Topography and Diseases of the Gold Coast," in the first volume of the "Epidemiological Transactions," says: "I have heard and read of negroes taking yellow fever, but in no case did it happen at Sierra Leone during its prevalence in 1837, 1838, 1839, 1847; nor, so far as I understand, in 1859; and no example of it occurred to any of my medical brethren in the course of their practice." This is certainly a remarkable testimony, when we consider that ninety-nine hundredths of the population of Sierra Leone are negroes. And to show that this is the immunity of negro blood, and not of acclimatization, I take the most remarkable experience of all, that of the French expedition to Mexico from 1862 to 1866. There was a heavy mortality from yellow fever among the motley gathering of troops at Vera Cruz in the summer of 1866; not only the French soldiers, but Arabs from Algiers, Indians from the interior of Mexico, and Creole troops from the West Indies, were decimated by it; whereas, in a body of four hundred negro soldiers from the West Indies, there were only three cases, with one death; and in a black regiment of five hundred men, raised in the Soudan and Nubia, there was not a single case.

If, then, we put together the facts of this remarkable disease: when we consider that its advent into the world coincided with the rise of the slave trade; that its habitat is or has been the ports of debarkation of the slave-trade, and those places in Spain and the West Coast of Africa to which slave-ships went on their return voyage; that its exacerbations have coincided with the most lawless period of the negro traffic; that it gained a footing in the ports of Brazil in 1849, when the slave-trade flowed into that channel; and that it has become endemic subsequent to 1853 on the Pacific coast of South America, in those parts of Peru which were the seat of an infamous coolie traffic—we can but see in all this concurrence of testimony a proof that Dr. Audouard was right in describing yellow fever as a peculiar form of typhus, originating in all its endemic centres in the filth of slave-ships, just as he showed that it had so originated, as a matter of fact, in two of the Spanish outbreaks. But if that evidence should not be enough, we have only to add the fact that the negro cannot take the disease, although it rages most in the very quarters where negroes live. The yellow fever still lurks about the wharves and shipping quarters of towns where cargoes of slaves used to be landed (e.g., the barracoon at Havana); and every few years, when the weather is at the hottest, it rises into a pestilence, as if it were the ghost of the slave-trade walking. But it passes by the negro, as if it recognized the ties of blood; and I want no other fact than that to prove that even this infection, belonging to the exogenous group, is but one step removed from perturbations of the normal life, and that it carries with it the indelible stain of its origin.

The connection between yellow fever and the dysenteric and other discharges of the negro body is only a part of that general connection between dysentery and typhus which has often been noticed in wars and famines. It formed the subject of a debate, in 1861, before the Epidemiological Society, in which the late Dr. Murchison gave an outline of the argument that he afterward maintained with so much learning and research in his treatise on "Continued Fevers." The celebrated cases of jail-fever, in which prisoners brought up at the assizes gave typhus to the judges and counsel and jury, are full of pathological interest; and it may be well, at the present day, to recall the fact, which arrested the attention of Lord Bacon, that the prisoners were not suffering from typhus themselves. But we need not go farther back than twenty years ago, or farther away than the city of Liverpool, for proofs of the *de novo* origin of a specific fever; no more striking proof was ever given of the genesis of typhus out of dysenteric and other filth than in the case of the Egyptian frigate which came from Alexandria to the Mersey in 1862 to be refitted. There were four hundred Arabs on board, who had suffered a good deal from diarrhoea and dysentery; they had met with rough weather all the way from Alexandria, and the hatches had been battened down for two or three weeks continuously. When the ship arrived in the Mersey, the 'tween decks were in a disgusting state of filth, and the pilot who took the vessel up the river remarked to his wife when he went home that that ship would be heard of again. He was himself the first victim, for he was seized with a fatal form of hemorrhagic typhus about a week afterward. More than one hundred of the crew were on the sick-list, chiefly from dysentery, but it was carefully ascertained that none of the cases were typhus. Most of the Arabs went to a public bath in their filthy state, and in a few days typhus broke out among the bath attendants. Some of the crew were admitted into the Southern Hospital for various non-contagious disorders, and there also typhus broke out.

All the facts of this most interesting case were communicated to the Epidemiological Society by the late Dr. Duncan, medical officer of health. It was Dr. Duncan's opinion, and also Dr. Cameron's, the present President of the Medical Section, that the outbreak was clearly traceable to the Egyptian ship and her filthy crew, but that it was not traceable to pre-existing cases of typhus, whether on the voyage or in Alexandria before sailing.

There is one other class of cases which I shall just mention—the cases in which the mere contact of human beings in an average state of health and cleanliness sets up various epidemic disorders among the inhabitants of remote islands, where strangers rarely come. Mr. Darwin, in his narrative of the voyage of the *Beagle*, quotes instances of this in the South Seas, on the excellent authority of Williams, the missionary; and it is to typhus that Mr. Darwin compares these cases. "It would almost appear," he says, "as if the effluvium of one set of men shut up some time together was poisonous when inhaled by others, and possibly more so if the men be of different races."

I shall take one other illustration of the doctrine of acquired autonomy, and I shall take both the facts and the doctrine from Sir Thomas Watson. The English troops that served in Egypt in 1801, under Sir Ralph Abercrombie, suffered much from the ophthalmia of that country, which is always brought on by exposure to cold after being heated, by the glare of the white and parched ground, by the dust in the air, and such-like causes peculiar to the climate of Lower Egypt. No one, in those days, thought that Egyptian ophthalmia was a specific infection. But some of the English soldiers returned with it uncured, and it soon became contagious in the home garrisons; and it was found, after a lapse of eight or nine years, that there were no fewer than two thousand three hundred and seventeen soldiers pensioners upon the public bounty from total blindness in conse-

quence of ophthalmia. Those who knew the disease as it occurs in Egypt denied that it was contagious, and those who saw it in England were as positive that it was contagious. Watson reconciles the two views. He says that "there is nothing absurd nor unlikely in the supposition that diseases may first arise from some other source, and then become capable of spreading by contagion;" and he says elsewhere: "My own creed upon the matter is this—that the disease may, and often does arise, independently of contagion, from the agency of ordinary causes of inflammation; and that, having so originated, it acquires contagious properties, which develop themselves only under circumstances that favor the propagation of most of the contagious complaints." A parallel to the Egyptian ophthalmia of 1801 may be found in certain cases of syphilis described by Baron Larrey in his surgical history of the same campaign. The Alexandrian syphilis, which the French troops contracted largely, was peculiarly free from "grave symptoms," and "easily cured;" but it proved very "obstinate and difficult to destroy" in those who brought it back with them to France.

In choosing to speak of infective diseases from a standpoint which is not the dominant standpoint of the time, I fear that I have laid myself open to the charge of taking advantage of a public opportunity in order to get a hearing for a somewhat peculiar view; but the words which I have just quoted from Sir Thomas Watson will show that this doctrine of common disorders acquiring specific power has not been absent from the thoughts of those who lived in the philosophical period of medicine. Nothing would be more agreeable than to adduce other instances of the same kind from the history of medicine, and I especially regret that time will not permit me to say something of this principle of autonomy as it was held by the thoughtful and talented writers who were known in Germany fifty years ago as the Natural History School. But in anything that concerns the natural history of disease, we may go direct to Sydenham, who was the author of the phrase, and in Sydenham we shall find a very explicit statement of the doctrine of an acquired autonomy and a pre-autonomous stage in the specific diseases. Sydenham uses the language of the humoral pathology of his time, but that matters little. The humors, he says, may, under certain circumstances, be raised to the dignity of a substantial form or to a species, a specific disease being one that takes its rise in the specific exaltation or specification of some juice of the body; and he expressly mentions the antecedent condition of the humor before it had put on its species—*antequam hanc induerat speciem*. If I have preferred to speak of the acquired autonomy of a disease, and of its pre-autonomous stage, I mean no more than Sydenham means here, as the context of the passage would show.

Sydenham compares these species of disease to the species of animals and plants, only that their life is an integral part of the general life of the body; and as we have an origin of species for animals and plants, it is natural to think of the origin of disease species. But there is a difficulty in the latter which the Darwinian problem is free from. In the origin of species we are dealing with individual things, each with its well rounded, independent life; but where is the individual life in disease? In my humble opinion, the germ will not serve our purpose, for, according to the great Darwinian analogy, the germ is always a part of the individual, and always presupposes the individual. The germ, or the sperm, is no doubt a peculiarly important part, and it is charged with the most marvellous representative powers, but it is always representative of the individual, and it derives its powers from the individual. Such, at least, is our only analogy.

If, then, we must have the individual to start with, before we can apply the "origin of species" to disease, we come back to the old question, how a morbid state of

the body can become a semi-independent thing, how it can exist, not in absolute independence of the body, but autonomous within it, an *imperium in imperio*. This is the perplexing question which I stated at the outset with reference to cancer, a disease which, in the popular estimation, is almost synonymous with a semi-independent life; and I quoted the words of Paracelsus: "In such a disease a man is himself and another; he has two bodies at one time, enclosed the one in the other, and yet he is one man." I have spoken to several metaphysical friends of the difficulty of conceiving how a mere state of the body, a complex or integrated morbid state, can become an individual existence with the power of propagating itself; but I cannot say that I have got anything satisfactory out of them. We shall probably have to settle this question within our own science as a part of the subject-matter of pathology. Pathology is indeed varied enough in its subject-matter. It studies disease on many sides, as the founder of this Association planned that it should be studied—the side of its anatomy and its physiology, of its geography and its ethnology, of its history and its natural history. Its aspects are as various and attractive as the fruit trees in the Mohammedan paradise. But there is nothing in all this boundless field of inquiry that is more likely to occupy the mind of the profession for years to come, as it has occupied it in times past, than the difficulty of conceiving how a state or condition of the body can become a species of disease.

THE PRACTICAL TREATMENT OF ABDOMINAL HERNIA.

By W. B. DEGARMO, M.D.,

NEW YORK.

1.

THE following remarks on abdominal hernia are placed before the profession with the sincere hope that they may lead, in some instances at least, to the better treatment of these affections, and to the more thorough study of a part of this subject, now much neglected.

It is probable that no subject within the domain of surgery has received more thoughtful and careful study than that which has been bestowed upon the surgical treatment of hernia from the days of Hippocrates to the present time. It is in the writings of Hippocrates that we find the first account of this affection that is in any degree correct. In later years it is described in the works of Celsus, Antoninus, Galen, Oribasius, Aëtius, and Paulus Aeginetus, the latter in the seventh century, and those first mentioned prior to that date. From that early period up to the present time we find prominent among other writers the names of Albucasis, Roger de Parma, Franco, Benedictus, Ambrosé Paré, Fallopius, Vesalius, Scultetus, Percival Pott, Scarpa, Lawrence, and Sir Astley Cooper.

In our own time the works of Wood, Dowell, Heaton, and others, relating to special operations or methods, will hardly bear favorable comparison with some of those earlier writings.

In the writings of the authors mentioned, and from the ably written articles on hernia contained in the standard works on general surgery, we can obtain accurate knowledge of the anatomy, pathology, and surgical treatment of these affections; in fact, so faithfully did Sir Astley Cooper study the subject that very little new material has been added to it since his time. The study of the management of and operation upon strangulated hernia has been exhaustive, and all teachers of surgery endeavor to impress their students with the importance of a thorough understanding of this branch of the subject. Many ingenious operations have also been devised for its radical cure, most of which receive stronger endorsement by their authors than by more impartial judges.

All of this is good in the line in which these studies

have been pursued, and beneficial in many instances, but they are of little service to the average patient suffering from, perhaps disabled by, a neglected hernia, who has not strangulation, nor the time, money, or inclination to attempt to obtain a radical cure. It is to this latter class that I desire to call the attention of the profession, and it is for their relief that I ask for a more rational treatment of hernia. It surely is as much the physician's duty to prevent strangulation as to relieve it when present. To treat disease only after it has arrived at its most dangerous stage is not, and should not be, in this instance, the practice of the conscientious physician.

In this country there are at a safe estimate five million persons suffering from some one of the various forms of abdominal hernia. In spite of poor treatment a few get well, others manage by their own ingenuity to prevent an increase in the bulk of their hernias, others by accident get something nearly suited to their cases; but a great majority of this vast number are growing worse every year until wholly or partially disabled, and many are saved from death only by timely and judicious surgical aid.

I speak advisedly when I say that the greater part of this suffering is entirely unnecessary, and due to the fact that when patients of this character apply to that source from which they should naturally expect and obtain relief, they are most frequently referred by their physicians to persons ignorant of the requirements of the case, who attend them on a purely speculative basis.

It is a crying shame that these numerous cases, so deserving of relief, so susceptible of alleviation in the hands of the professional man, are still neglected by the majority of practitioners, who shift all responsibility to the druggist, instrument maker, equally incompetent truss vender, or allow them to drift into the clutches of that chief of charlatans, the self styled "rupture doctor," who is ever ready with his testimonials of cure to exact an exorbitant fee from his easy victim.

It would be a poor surgeon who should leave the application of splints in the hands of the manufacturer, and devote years of study in trying to remedy the bad results sure to follow such practice, and yet this is done in cases of hernia. It needs no statistics, however, to prove that there is more danger to life, and of disability in an ordinary hernia, than in an uncomplicated fracture of the humerus, allowing that both are equally neglected. Why this difference in practice in the two cases? Why is the one dismissed with scarcely a second thought, while the other receives the surgeon's most careful attention? The answer, I believe, may be found in the prevailing, but certainly erroneous idea, that for a person afflicted with hernia there is positively no cure, and probably no relief.

To inform a patient suffering from hernia that no relief can be obtained, sending him off to buy a truss, thus dismissing the case, is doing that person a very great injustice, and the writer has seen most unfortunate results following this common practice. On the contrary, the sufferer should be informed of the importance of remaining under the observation of his physician, and carefully instructed in the proper use of the necessary appliance.

An eminent authority across the water has truly said: "The expediency of judiciously pursuing the mechanical treatment of every variety of hernia cannot be too strongly urged upon the laity by the profession. In both sexes it should be carefully conducted the moment that the slightest protrusion shows itself. Whether the hernia occurs in infancy, youth, at middle age, or at later periods of life, if properly watched and judiciously supported, it usually gives but little trouble; in many cases it is even cured. But, on the contrary, if it be neglected, increase in bulk, and sooner or later diseased states of the rupture, often leading to the death of the individual, will almost infallibly occur."¹

¹ Holmes' System of Surgery, vol. ii., p. 676.

Percival Pott, writing in 1779, recognized the importance of giving these cases early and careful attention in order to secure the best results. It is to be regretted that the writings of this and other authors have not made a deeper impression upon the general profession. He says: "There are many circumstances attending ruptures which will require frequent assistance in order to render a cure more probable, and there are many ruptures in persons of mature age which will admit of perfect cure if properly and judiciously managed from the first."¹ The remarks of the same author upon the charlatans who thrive upon this class of cases is, it is to be regretted, still applicable: "It has in all times, from the most ancient down to the present time, rendered those who labor under it subject to the most iniquitous frauds and impositions. No disease has ever furnished such a constant succession of quacks as ruptures have." In this, as in other instances, those branches of practice overlooked or neglected by reputable and educated physicians are the fields in which quackery best thrives. By keeping these cases within the profession, and bestowing the same amount of time and study upon them now given to surgical cases of even less importance, methods of treatment would improve, results now considered impossible would be attained, and sufferers will not, as heretofore, be obliged to submit to the impositions of incompetent and dishonorable persons.

As the limits of this article will not admit of a detailed account of the proper treatment of each variety of hernia, I shall at present make only a few such suggestions as are applicable to all cases; at a later date I intend making some observations on the best practical methods of treating each form, in order to secure the greatest number of cures, and the maximum amount of improvement in those considered incurable. In order to form an opinion in any degree correct upon which a prognosis may be based, it is important at the outset to get a full history of the cause, development, and past treatment of each individual case. A hernia produced suddenly by heavy lifting, violent coughing, or other similar causes, is far more susceptible of cure than one coming on gradually with a relaxed and flabby condition of the abdominal parietes, and a distinct hereditary predisposition. Hereditary predisposition will be found an important factor in some cases. The writer has under observation one family in which nearly every male member for four successive generations has been afflicted with inguinal hernia; another family where in three generations almost all of the female members have suffered from either umbilical, inguinal, or femoral hernia.

The exact cause of this predisposition is, I think, left for future study to determine. Sir Astley Cooper believed it due to the width or shape of the bony pelvis, but, after accurate observations under favorable conditions I am unable to endorse this view, having found by diagrams representing the exact shape of a section of the pelvis, taken from several members of the same family in which hernia was undoubtedly hereditary, that they did not on comparison show any striking resemblance in size or shape.

By a thorough search for the immediate cause of a hernia much may be accomplished in many instances, especially if the case be a recent one, as, if the cause be found to be one which may be removed, the chances of complete cure are thereby greatly enhanced. For example, if a person has recently produced a hernia by straining at stool, due to constipation, this cause must be removed at once, and then with suitable treatment, immediately applied, there is more than a mere chance of complete recovery. The same remarks apply with equal force to cases of stricture and to children suffering from congenital phimosis.

The writer has seen several instances wherein the latter has produced the most rebellious hernias, which

have entirely recovered when the cause was removed. At the Children's Hospital, London, Mr. Kempe found in fifty consecutive cases of congenital phimosis, thirty-one cases of hernia which had developed since birth. Improvement began in every instance as soon as circumcision was performed, and in five cases immediate cure of the hernia resulted.¹

One of the most obstinate scrotal hernias the writer has ever had to contend with was caused by vesical calculi in a patient over fifty years of age. After the operation for the removal of the stone the hernia so far improved as to enable him (contrary to advice) to go days at a time without his truss and still no protrusion occurred.

The variety and condition of the hernia should receive careful consideration. It is quite essential in inguinal hernia, for instance, to determine with certainty whether we are treating a direct or an oblique protrusion, as in the former the centre of pressure used for its retention should be at the external ring, while in the latter it is of the first importance that it should be worn over the internal ring. The methods of diagnosis are so fully given in all text-books on surgery as to make their mention here unnecessary, and their treatment will be taken up later.

Is the hernia reducible? In the majority of cases it will be so found; in a few, attempts at reduction will not be attended with success. Do not decide this point hastily, however, and thereby consign your patient to the lifelong danger, discomfort, and disability sure to result from irreducible hernia. In order to illustrate the importance of this statement the following case is cited:

E. C.—, merchant, aged thirty-eight, consulted me, September 10, 1879, respecting a very large scrotal hernia, which had not been reduced for six years. Originally small and easily controlled, it had arrived at its present condition through the use of inferior trusses, bought of the druggist to whom his physician had sent him, selected and applied according to his own judgment. Now, after having abandoned all support for several years, it has been pronounced, by four physicians, irreducible hernia, and is so troublesome as to unfit him for business. In character it is an entero-epiplocele, the largest part of the protruding mass being omentum, which in places appears firmly adherent.

Gentle but constant taxis, with hips elevated, was continued for *one hour*. No perceptible effect was produced, and the patient was instructed to return to his hotel and remain in bed twenty-four hours, the diet to be the lightest possible.

September 11th.—Taxis again employed for about half an hour, and with better results, about one-third of the mass being returned. Efforts at reduction discontinued, patient instructed to remain in bed as before.

September 12th.—After twenty minutes' trial entire mass gradually returned within the abdomen. A suitable retentive appliance was adjusted, and instructions given that should colic, nausea, or vomiting occur, it was to be removed at once and the hernia allowed to descend; patient to remain in the recumbent position. About one hour later discomfort in the umbilical region was experienced, soon followed by vomiting. Support removed and greater portion allowed to descend, after which unpleasant symptoms soon subsided. No further attempts at retention were made on this day.

September 13th.—Hernia reduced with very little difficulty, and retained for three hours before discomfort was occasioned.

September 14th.—Support worn six hours, and on the following day all day.

Four months later I made the following note in my case-book: "Improvement in this case rapid, and to an unexpected extent; hernia never descends, even under

¹ The Chirurgial Works of Percival Pott, vol. ii., p. 48.

¹ The Lancet, July 27, 1878.

light pressure. Attends actively to his business, and experiences no inconvenience either from his hernia or the appliance worn." This case has been given in full because it clearly illustrates three very important points, viz.:

First.—That an apparently irreducible hernia can, in some instances at least, by judicious and persistent taxis be returned to the abdominal cavity.

Second.—That extreme caution is absolutely essential to the safety of the patient, after as well as during reduction.

Third.—That great improvement is possible, under favorable conditions, even in extreme cases; that the patient can be brought from disability, suffering, and the constant dangers of strangulation, to a condition closely approximating a cure.

In employing taxis only the most gentle manipulation is admissible, and the patient should not be subjected to any amount of discomfort. The necessity of closely watching the case after reduction can not be over-estimated; omentum after a long residence outside of the abdominal cavity becomes hardened and changed in character, so that when returned it acts upon the peritoneum as a foreign body. Petit has recorded a death due, as was found post mortem, to peritonitis produced by returning and keeping within the abdomen omentum which had long been protruded.

These hernias of long standing are worthy of the surgeon's most careful and persistent attention, and when this is given, he will frequently be rewarded by the most gratifying results.

M. Thiry, in a carefully written paper read before the Royal Belgian Academy of Medicine, arrives at the following conclusions:

First.—Old hernias of large extent, constituting a variety of eventration, are susceptible of reduction in most cases.

Second.—The large volume of a hernia is never a contra-indication to its reduction, although it necessitates the adoption of certain precautions, and the employment of considerable time.

Third.—The diminution in the capacity of the abdominal cavity in old hernias is never antagonistic to a slow, methodical, and progressive taxis.

Fourth.—By slowly re-entering the abdominal cavity the extended parts gradually resume their former places.

Fifth.—The best method of reduction is "compressing taxis," which consists in only restoring organs to their natural position after they have been relieved by pressure of any vascular engorgement. Those organs which effected an exit last should be first replaced."

In attempting the reduction of these old hernias considered irreducible, it is best that the patient be fully informed at the start of the importance of having the protruding viscera returned to the abdominal cavity, otherwise he may become impatient under the confinement to bed.

In hernias of this class, when strong pressure is necessary to retain the mass after reduction, great trouble is sometimes experienced in keeping the skin beneath the pad in a healthy condition. To accomplish this, strict cleanliness of the appliance as well as of the person is absolutely essential, combined with such local medication as may be indicated. In the hands of the writer the following powder applied beneath the pad on a thin layer of absorbent cotton has proven more efficient in action than any other means resorted to for hardening the skin and keeping it healthy:

R. Amylum.....	iv.
Creta gallica.....	ij.
Alumen ust.....	i.
Acidi boraci.....	ij.
Acidi carbolici,	
Ol. limonis.....	āā. ʒ ss.
Ft. pulv.	

The parts should be thoroughly washed every night, and freshly powdered absorbent cotton placed beneath the pad every morning for the first week that the support is worn. The results will fully compensate for the extra trouble involved.

The writer in his earlier experience in the treatment of hernia, had the importance of employing these precautions impressed upon him by the following circumstance: The case was an extremely obstinate oblique inguinal epiplocele, and very strong pressure was required for its retention. After the adjustment of the appliance, which was perfectly successful in its retentive action, the gentleman failed to present himself for examination on the following day as requested, and at the end of one week I was asked to see him at his house. I found that he had experienced no great amount of discomfort, but on removing the support on the night previous, the skin had adhered to the pad, and he had removed a piece of the integument which had sloughed away, corresponding in size with a silver half-dollar, leaving the subcutaneous tissues completely exposed. Suitable dressings were immediately applied, but with the most careful attention the patient was confined to the recumbent position for three weeks before the process of healing by granulation was complete, and for this amount of discomfort and detention from business he had only himself to blame for disobeying the instructions given him.

THE DIAGNOSTIC SIGNIFICANCE OF IMMOBILITY OF ONE VOCAL BAND.—Dr. J. Solis Cohen, in a paper in the July number of the *American Journal of the Medical Sciences*, points out: *First*, that laryngoscopy may sometimes be the sole or most efficient means of diagnosis in affections located exterior to the larynx; and *second*, that a liability to error might often be incurred, were we to place too exclusive a reliance upon the objective symptoms, as presented by the image seen in the laryngoscopic mirror. From a study of cases under his observation he concludes: 1. That whenever the left vocal band is immobile in abduction, or in the cadaveric position (positions in which the patency of the glottis is not interfered with), and there is cough or dyspnoea (or both), without cardiac or pulmonary lesion to account for these symptoms, we are justified in suspecting aneurism of the aortic arch; and difficult deglutition will be almost certainly confirmatory of the diagnosis, notwithstanding the absence of tumor, pulsation, thrill, and bruit. The only, and exceedingly improbable source of error, would be intrathoracic neoplasm. 2. That ankylosis of the crico-arytenoid articulation may fairly be suspected in cases of immobility of one vocal band, not referable to mechanical interference with the transmission of nervous force; unaccompanied with evidence of central or local nervous disease; and in which failure to respond to appropriate treatment will warrant us in excluding muscular atrophy. But the diagnosis can be finally established only by the application of direct pressure to the affected arytenoid cartilage. 3. That whenever one vocal band is immobile in the cadaveric position or in abduction, and there are no other signs or symptoms to assist the diagnosis, ankylosis being eliminated, we should not be satisfied with a diagnosis of neuropathic paralysis; but should keep the patient under observation with a view to detecting the earliest manifestation of aneurism, consolidated lung, or other mechanical cause for the impaired innervation.

WESTERN CRITICISM.—Bellevue Hospital Medical College, while ostentatiously proclaiming in her announcement her fidelity to the Code of Ethics, places no restrictions on the admission of students to her classes, other than that involved in the price of her tickets. It is, of course, much more important that a physician be ethical than that he should be at all prepared by previous education to take up the study of medicine. Great is reform!—*Medical Age*.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 11, 1883.

THE GERM THEORY OF TYPHOID FEVER AND THE TREATMENT OF THIS DISEASE BY SALICYLATE OF BISMUTH.

THE tendency of the age is undoubtedly to account for all the contagious febrile affections, as well as many chronic diseases, by the hypothesis of a specific microphyte, whose ravages constitute the pathogenetic element. This tendency is exemplified in the theory, recently formulated, and ably supported by Klebs, of Prague, and Eberth, of Zurich, as to the etiology of typhoid fever.¹

According to these pathologists typhoid fever is due to a peculiar microbe which presents itself in the form of rods or filaments, some of which contain spores. Between the rods and the filaments transition forms are observed, which make it probable that the latter are derived from the former.

These micro-organisms have been found by Klebs, in accordance with the period of the disease from which death resulted, in the following localities: 1, in the intestine, first in the glands of Lieberkuhn, later in the interglandular tissue and in Peyer's patches, still later in the submucous cellular tissue, and even in the muscular layer; 2, in the mesenteric glands; 3, in the spleen; 4, in the lungs (the parts affected with hypostatic pneumonia); 5, in the brain.

He has also found them in abscesses complicating typhoid fever, in ulcerations of the larynx, in the kidneys, the myocardium, etc. In these various sites he has detected the same microbe, and in numerical abundance proportioned to the disorder of function of the organ where the bacillus has been found. Klebs has made many cultures of the microbe, and has inoculated animals with the final product, reproducing in hares, pigeons, guinea-pigs, etc., the characteristic anatomical lesions of typhoid fever.

Eberth, of Zurich, after an independent series of investigations, has found in the lymph-organs of the abdomen—intestinal mucous membrane, mesenteric glands, spleen—certain rods whose characters correspond with those noted by Klebs. These rods have, in fact, been identified with Klebs' bacilli.

Klebs gives a graphic *résumé* of the march of this malady. The bacillus typhosus, or its spores, are taken into the mouth and pharynx in the air of respiration and

are carried to the stomach with the saliva or food. Arriving in the small intestine they produce by their multiplication a diffuse catarrhal inflammation, and commence to penetrate the mucous membrane. This anatomical stage corresponds to the period of incubation of the disease, a period characterized by anorexia, prostration, and a slight febrile movement. At this epoch the disease is still local; it is not till later, when the bacillus has effected an entrance into the blood and has invaded the organs, that we witness the second "classic" stage, the stage of infection, characterized by fever, cerebral symptoms, etc. At the same time the intestinal inflammatory process concentrates itself on Peyer's patches, which finally become necrosed and eliminated. The microbes, moreover, may multiply in the spleen, brain, lungs, and produce there grave disorders.

It sometimes happens that the bacillus first undergoes development in the lungs; the disease then commences as a pneumonia (typhoid pneumonia); at the autopsy the intestinal lesions (when they exist) are more recent than the pulmonary lesions.

The primitive lesions of the intestine are not always in such direct relation to the secondary lesions of other organs, that to the intestinal alterations, however extensive and profound, corresponds a proportionate perturbation of other functions of the economy. The autopsy often demonstrates that the intestinal ulcerations may be most marked and grave, at the same time that the general infection may have been almost nul; such are the cases described as *typhus ambulatorius*, or walking typhoid. On the other hand, with general infection and serious constitutional symptoms, the local intestinal lesions may be inconspicuous or wanting. In a word, typhoid fever comprehends two distinct diseases; the local intestinal lesion, and general infection with localization in different organs. These two factors of this complex disease are synchronous in a part of their duration. The first precedes the second, and the latter is in full evolution while the lesions of the former are undergoing reparation.

The germ theory of typhoid fever is far more probable than the chemical theory; in fact, we can imagine no chemical ferment or "poison" which is capable of producing such phenomena, while the hypothesis of a *contagium vivum*, infinitesimal in its commencement, pululating in the system, and invading important vital organs, which are robbed by it of their life-sustaining oxygen and pabulum, till the enviroing conditions are no longer favorable for the maintenance of the parasite, well explains all the striking phenomena of the disease. Moreover, important inductive evidence is every year making the microphyte theory less an hypothesis and more a fundamental fact in pathology. The inoculation experiments of Klebs, above alluded to, constitute the kind of proof now demanded.

Almost all pathologists being convinced of the germinal origin of all contagium, there is a dominant desire on the part of therapeutists to attack the microbe by suitable germicides in the alimentary canal or in the blood, to prevent its multiplication and effect its destruction. There is very general agreement that we are not yet in possession of any sure and safe means of combating the germinal *materies morbi* when once it has effected entrance into the blood. No one has more clearly shown

¹ Bulletin gen. de Therapeutique, June 30, 1883, Desplat's article, to which we are indebted for this summary.

this than professor Germain Sée in a late lecture.¹ Quantities of any known antiseptics, such as would be necessary to rid the blood of the parasitic contagium would be toxic and speedily fatal to the organism. This is notably the case with such germicides as bichloride of mercury, chlorine, iodine, carbolic, and even salicylic acid. Salicylic acid, the only acid seriously to be thought of in this connection, has never yet been given in sufficient doses to arrest typhoid fever in its march, or even materially to modify its evolution. Professor Sée has known of a rheumatic patient who, while taking ten grains every two hours of salicylic acid for several days, was nevertheless attacked by typhoid fever, which pursued its usual course.

Being then debarred from any safe and certain chemical antidotes against the morbid bacillus when it has pervaded the system, our therapeutical efforts are diverted to other indications, such as the support of the vital forces in the struggle in which they are engaged. But can we do nothing to effect the destruction of the disease-germ while it is in the alimentary canal, before it has penetrated the tissues or gained the circulating fluids? Not a few distinguished therapeutists have answered this question in the affirmative, notably Gueneau de Mussy, Herard, Hallopeau, Liebermeister, Wunderlich, and in this country Dr. James C. Wilson and Roberts Bartholow.² The treatment of the last two authorities is essentially identical. Calomel is given in full purgative doses several times during the first week. This is exhibited for a double purpose, to restore heat production and to destroy typhoid germs in the intestine. Iodine is given throughout the disease in combination with carbolic acid, or as Lugol's solution. Bartholow's formula is two parts tincture of iodine to one of strong carbolic acid; of this from one to three drops every three hours during the day and night.³ By this medication it is intended to arrest the multiplication of germs in the intestine and prevent fermentation.

Professor Henri Desplats, of Lille, is favorably known by his numerous theses on the antiseptic treatment of fevers, especially by a memoir published last year on the treatment of typhoid fever by carbolic acid. After long experimentation with various salicylates in typhoid fever, he has found in the salicylate of bismuth the great desideratum. It is sparingly soluble, and therefore is more likely than most medicaments to escape absorption in the stomach and to reach the diseased intestine. It moreover has an energetic action on the organized ferments, and is a bactericide of great power. Taken during the prodromic period, when the infection is purely intestinal, the microbes not having entered the blood and tissues, its efficacy is greater; in Dr. Desplat's experience it has even had a marked abortive action. Thus, out of twenty cases reported by him, eleven (or more than one-half) treated in the first stage were cut short in four or five days under the free use of salicylate of bismuth. At least this is the belief of the professor, who gives the particulars of these cases with great minuteness,

showing that the patients had all the characteristic symptoms of the disease with varying degrees of severity. In four cases the bismuth salt had a very decided moderating effect on the temperature, but the disease was prolonged by complications. In five cases, all of which were very grave, the action of the medicament was null. The ordinary dose was about a scruple. This was repeated sufficiently often, so that the daily quantity taken should equal about six grammes (or about one drachm and a half). In some instances, where the fever-heat was excessive, the salicylate was given in one full dose of three, or even six drachms, but these large doses proved somewhat depressive. The medicament is not unpleasant to the taste and is easily borne. In short, the perusal of this article seems to justify the hope that in the salicylate of bismuth we have a new medicament of very great antiseptic value.

PREHISTORIC SURGERY.

In a paper read before the Surgical Section of the Fifty-fifth Convention of German Naturalists, Dr. Tillmanns presented some interesting conjectures concerning the state of surgical art in the stone age (*Centralblatt für Chirurgie*, June 23, 1883). He first reviewed the surgery as practised at the present time by peoples supposed to occupy the same plane of development as prehistoric man in the stone age. Then, from articles found in the caves of the men of this age, he formed his conclusions concerning their surgical practice. Among the peoples still living in the stone age he reckons the Australians, the South Sea Islanders, and the Esquimaux. Dr. Miklucho-Maclay has given an account in the *Zeitschrift für Ethnologie* of castration and ovariectomy as practised among the Australians. He states that girls are robbed of their ovaries in order that they may serve as "hetaïra" to the young people. The operation is performed through an incision by means of sharp flints, on each side parallel to Poupart's ligament. The operation looking to the sterilization of men is performed by cutting away the under wall of the urethra from the meatus to the scrotum. This is done by means of a knife formed of a splinter of quartz set in a handle made of the dried sap of an indigenous tree. The South Sea Islanders trephine for injuries of the brain or skull. A T-shaped incision is made through the scalp and the bone scraped away with a splinter of glass. The operation is fatal in about one-half of the cases. In case of recovery the hole is covered with a thin piece of coconut shell. If the brain is found to be injured the destroyed portion is replaced with a piece of the brain of a recently killed hog. This procedure is said to promote recovery. The natives of Tahiti possess a large surgical armamentarium, consisting of flints, bistouries made of shark's teeth, sharpened bones, etc., similar to those found in the caverns of the stone age. They make saws also from shark's teeth. The Esquimaux produce abortion by pressing or striking against the womb with a whip handle. They also use the sharpened rib of a walrus or a seal, which they guard with leather and introduce into the vagina to puncture the membranes.

Much has been learned of the operation of trephining in prehistoric times from the researches of Prunières and

¹ *Traitement de la Fièvre typhoïde*, Paris, 1883.

² *Utile Wilson on Continued Fevers*, p. 228. New York, William Wood & Co. Also an able statement of Wilson's and Bartholow's antiseptic method of treating typhoid fever in the *New York Medical Journal*, vol. xxxvii., page 27.

³ *Boston Medical and Surgical Journal*, February 1, 1882.

Broca. The former found a so-called "rondelle," an oval piece of bone, one and one-half by two inches in diameter, taken from the parietal bone, in the excavations at Lozere. Such "rondelles" were worn as amulets. They were taken from the skulls of those who in life had survived the operation of trephining. Such men were regarded as holy. After their death fragments of bone were taken from about the trephined part and worn as charms. Many skulls showing this treatment were found. The operation seems to have been performed by scraping away the bone with a flint, as the oblique edges of the hole in the skull would indicate.

THE ALLEGED CURABILITY OF TUMORS BY THE PARENCHYMATOUS INJECTIONS OF OSMIC ACID.

SOME time ago we had occasion to comment upon a report published by Dr. Delbastaile concerning the favorable results obtained in the treatment of tumors by the injection of osmic acid. The cases referred to were observed at Winwarter's clinic in Liege. A soft sarcoma, the size of a child's head, seated upon the right side of the neck, after an unsuccessful attempt at extirpation, was treated by the daily injection of three drops of a one per cent. aqueous solution of hyperosmic acid. After fourteen days the new growth was softened and discharged through the wound in the skin. In a month the tumor had entirely disappeared without any unfavorable local or general symptoms. Equally favorable results were obtained in the case of a multiple lymphoma, cervical adenitis, and a sarcoma near the shoulder.

Upon the strength of this report, the late Professor Bruns, of Tübingen, was led to make a trial of the remedy in a number of instances. The cases are reported at length by Dr. Pfeilsticker in the *Med. Correspondenzblatt des Württemb. Aerzt Landesvereins* of May 31, 1883. There were four cases of multiple tubercular lymphomata, one of malignant lymphoma of the neck, and one of a sarcoma, the size of a man's head, upon the left side of the chest. Unfortunately, not the slightest effect was observed in a single case, even after long-continued trial of the hyperosmic acid injections. The procedure was painless in most instances. The only obvious result, however, was the matting together of the tumor and the neighboring tissues, thus increasing the difficulty of extirpation by the knife. This want of success is explained by the strictly local action exerted by the acid. It causes a necrosis of the tissues at the point of injection, but produces no change in the surrounding parts. Evidently modern surgery commands better methods of dealing with neoplasms than the hypodermic injection of osmic acid.

FAVORABLE RESULTS OF TRAINING UPON THE SENSE OF COLOR.

It has been stated by Magnus and others that color blindness is capable of correction by means of special training. And this seems not at all improbable, reasoning from analogy, since other senses may be developed to such a wonderful degree in certain directions by careful education. An observation made recently by Dr. W. Kroll is of interest in this connection (*Deutsche Medicinal-Zeitung*, June 7, 1883). He examined a large number of men in Crofeld and its vicinity, but found

only 0.6 per cent. affected with color-blindness. The usual proportion is three per cent. of all examined. The principal industry of Crofeld, for nearly two centuries, has been the manufacture of silk stuffs and velvet, and it seems reasonable to attribute the low percentage of color-blindness among the inhabitants to the education of their sense of color perception consequent upon their occupation. It would be easy to pursue these investigations further among operatives in print works and in other places where colored materials are manufactured in this country, and the results thereby obtained might prove to be of interest, and would certainly have a real practical value.

News of the Week.

CONCERNING ACONITIA.—Dr. J. O. Tilton writes us to know if the granules of aconitia ($\frac{1}{200}$ grain Duquesnel) administered according to directions given in an editorial article in this journal, July 14th, are safe. We have seen nothing, and we are able to find nothing which would lead us to fear any unfavorable results from this drug given with the precautions which we have urged, namely: not to take more than $\frac{1}{4}$ milligramme at a time, and not to repeat the dose oftener than once in three hours, and not to exceed 2 milligrammes ($\frac{1}{30}$ grain) a day. Granules of aconitia, containing $\frac{1}{200}$ grain, are sold in our drug stores. These granules contain somewhat more than $\frac{1}{4}$ milligramme, and should be used with more caution. We have prescribed these granules in several instances with good effects, directing one granule every four hours till some tingling of the tongue, pricking of the face, or tightness about the temples, was experienced. Generally decided amelioration has attended these symptoms, which indicate that the physiological effect of the alkaloid is being realized. In fine, it cannot be claimed that $\frac{1}{200}$ grain aconitia is in any sense a poisonous or a dangerous dose, and we should not hesitate to repeat it every four hours till either the pain is subdued, or till some or all of the minor toxic phenomena above mentioned are felt, watching the actions of the medicament, and being ready at any time to interrupt its administration, as we would do with any powerful remedy.

THE ADDRESSES BEFORE THE BRITISH MEDICAL ASSOCIATION.—We have the pleasure of presenting in the present issue the addresses of Drs. Waters and Creighton, delivered before the British Medical Association last week. These comprise, with Mr. Harrison's address (published last week), all those delivered before the General Meeting of the Association. Both articles will be read with interest on this side of the Atlantic, and will amply repay the extra space given them. Dr. Creighton's able exposition of his subject, and the arguments used in support of his views will be especially interesting and instructive to advanced pathologists and earnest students in the higher professional studies.

THE CHOLERA.—The news from Egypt is becoming less alarming. It is said that some of the leading physicians of Smyrna do not regard the scourge as cholera. By last report there were thirteen deaths in Alexandria, and the number of cases of the disease was decreasing in the interior.

NEW YORK POST-GRADUATE SCHOOL.—DR. A. H. Smith has been elected Professor of Clinical Medicine and Therapeutics, dividing the former chair with Dr. T. E. Satterthwaite, Professor of Pathology and Clinical Medicine. Dr. Alex. J. C. Skene, of Brooklyn, has been elected Professor of Gynecology, dividing the chair with the present incumbent, Professor B. F. Dawson.

OUR CABLE DESPATCHES.—We beg to return our thanks to the numerous subscribers who have sent us so many kind congratulations regarding our cablegrams of the recent meeting of the British Medical Association.

THE ATLANTIC STEAMSHIP SERVICE.—A deputation of the British Medical Association and several members of Parliament called recently upon Mr. Joseph Chamberlain, President of the Board of Trade, and asked him to appoint a committee to consider the inadequate medical and sanitary management of Atlantic steamers. They commented strongly upon the want of proper precautions on emigrant vessels, from which a large annual sacrifice of life resulted. They suggested that ship-owners be compelled to increase the pay of ship surgeons, and that the American Government be requested to contribute a small sum toward the expenses of vaccinating passengers on board of vessels. Mr. Chamberlain replied that he intended to introduce in Parliament, in 1884, a bill dealing with the subjects mentioned and amending the shipping act.

THE GERMAN POLIKLINIC OF THE STATE OF NEW YORK.—We are informed that some of the German physicians of this city, have organized a Poliklinic (with an i). It is located on Sixth Street.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CHOLERA—THE WATER-SUPPLY OF LONDON—MEDICAL HONORS IN LONDON AND DUBLIN—THE CASE OF DR. BLADES—THE LATE DR. STEWART.

LONDON, July 28, 1883.

CONTRARY to expectation, cholera has continued to spread in Egypt. The Government are doing what they can to arrest its spread, and have just sent out twelve civilian medical officers to the affected district. Meanwhile a conference of medical officers of health on the subject has been held and arrangements made in readiness in case cholera should unfortunately reach our shores. The possible advent of cholera has again revived the question of a purer water-supply for London. We still drink only filtered river water in London—mostly from the Thames—and although the companies now have their intake higher up than London, the river is still not wholly free from sewage contamination from towns higher up the stream, although of late years great efforts have been made to lessen its pollution from such sources. There seems to be not the faintest chance of a water-supply for London from any purer source so long as the supply rests with the water companies. We shall have to wait, first, till the next session of Parliament for the London Municipal Bill; second, for a purchase by the new municipality of the companies' works and rights; third, for the construction of a conduit from a purer source. Meanwhile, while not improving the quality of the water, several of the companies have taken advantage of their parliamentary powers to largely increase

their rates, which, by the way, may probably prove an advantage from a sanitary point of view, as it will direct the attention of the ratepayers to the general subject of London water-supply.

Two more baronetcies have just been given to London medical men, viz., to Dr. Andrew Clark and to Mr. Prescott Hewett. The former is the Premier's medical attendant, and has one of the largest practices in London as a general physician, having the repute of realizing over twelve thousand guineas a year. He has written on pulmonary diseases, especially on "Fibroid Phthisis," and lately delivered an important address on "Renal Inadequacy." Dr. Clark is an enthusiastic advocate of the temperance cause. He is at present senior physician to the London Hospital, and is very popular with his students. Dr. Clark is, if not the most eloquent, one of the *readiest* speakers in the profession. For getting up and delivering a lengthy impromptu speech on any subject he is—within the profession—probably unequalled.

Mr. Hewett holds an equally important position on the surgical side of the profession, being senior surgeon to St. George's Hospital, holding several appointments to the Royal family, and is an important contributor to "Holmes' System of Surgery." Mr. Hewett enjoys an extensive consulting practice among the élite of fashion at the west end.

Some Irish honors recently proffered have given less satisfaction. The lesser dignities of knighthoods have been offered to Surgeon George Porter and Dr. Banks, both of Dublin. The latter promptly declined the honor as not commensurate with his professional position; the former has, after deliberation, finally accepted. The feeling among the profession in Dublin is very bitter on the subject, and a deputation of medical men has waited on the Lord Lieutenant who told them he could not intervene in the case of honors awarded by the Crown.

The recent apparently arbitrary dismissal of a police-surgeon for his alleged neglect of a constable suffering from obscure diabetic symptoms terminating fatally, continues to excite attention, and *The Lancet* has started a memorial to the Home Secretary on the subject.

One of the latest losses to the London profession by death is that of Dr. A. P. Stewart. Dr. Stewart practised as a general physician at the West End for forty-three years, and was a very widely known member of the profession. Very early in his career he wrote a lengthy paper in which he differentiated typhoid and typhus fever, and to a large extent anticipated Sir W. Jenner's later but more complete researches. But Dr. Stewart did not follow up the clue he had obtained, and thus did not acquire the fame and position which might have been his. He was on the staff of the Middlesex Hospital for many years, and at the time of his death Consulting Physician to that institution. He also lectured at the school on materia medica and medicine successfully. He held important offices as a member of the British Medical Association, and after being for many years one of the secretaries to the Metropolitan Counties' Branch (a post in which he was succeeded by Dr. Farquharson, now M.P.) was presented with a handsome testimonial subscribed among the members. He was once offered the presidency of the Branch but declined it. Dr. Stewart was one of those of whom it can be truly said that he sought not the material rewards of his profession. His practice was never extensive. He was nevertheless beloved by all with whom he came in contact. His manner was genial and attractive, his character consistent and upright. He was well-known for his interest in all religious movements, and he made an attentive study of the revised version of the English Testament. He was a Scotchman by birth, and distantly related to the family of the Prime Minister. Had Dr. Stewart been more energetic and business-like he might have reaped a richer harvest in practice, but he was not pushing, and even declined to lecture at the College of Physicians when asked to do so a short time since.

Progress of Medical Science.

SALICYLATE OF SODA IN DIARRHOEA.—In an article on the pathology and classification of the various forms of diarrhoea, and on the indications for the employment of salicylate of soda in this affection, Dr. Calleza concludes as follows: 1. The products of the putrefaction of the contents of the intestinal tube are the sole cause not only of a number of varieties of idiopathic diarrhoea, but also of many secondary diarrhoeas, in which the pre-existing disease has engendered a predisposition to decomposition. 2. Salicylate of soda is the most efficacious agent for preventing putrefaction in the intestinal tract without interfering with the normal digestive processes. It should always be employed when the stools have a putrid odor, especially if this character has been noted from the commencement. 3. Two or three doses of fifteen grains each per diem are sufficient for the speedy cure of strictly idiopathic diarrhoea. 4. In the secondary forms of the disease (which are far less common) a trial may be made of the salicylate rather as a prophylactic measure than with the hope of any marked therapeutic effect. 5. In syphilitic and phthisical diarrhoea, in that accompanying visceral abscess, especially of the liver, and in dysentery, salicylate of soda has produced the best results.—*Lyon Médical*, May 20, 1883.

THE USE OF COFFEE IN STRANGULATED HERNIA.—Dr. Antonio Sarra relates that he was called one evening to attend a man, sixty-three years of age, suffering from a strangulated femoral hernia. The patient was nearly moribund, there was no appreciable radial pulse, the face was pinched, the extremities were cold, and the attempts to vomit were almost incessant. Happening to remember the report of a similar case relieved by coffee, Dr. Sarra ordered an infusion of this substance to be employed as a drink and also externally, and then took leave of the patient, warning the family that death was inevitable unless a prompt amelioration ensued. Upon returning early the next morning he was surprised to find his patient in perfect health. The man stated that soon after taking the coffee he experienced a feeling of warmth and returning strength, then a large quantity of gas was expelled above and below, and when he put his hands upon the tumor it at once slipped back into the abdominal cavity, much to his astonishment as well as joy.—*Lyon Médical*, May 20, 1883.

CARDIAC AND PULMONARY SYMPTOMS DEPENDENT UPON GASTRO-HEPATIC TROUBLES.—In an exhaustive memoir upon this subject, embodying the results of a large number of observations, Dr. Barié concludes as follows: 1. Certain dyspeptic conditions arising from the stomach, intestine, or bile-ducts react upon the cardio-pulmonary apparatus and occasion morbid phenomena, which may be divided into four clinical groups: A. In the first form the heart alone is affected, as evidenced by palpitation and intermission of the pulse. B. The second form is characterized by phenomena affecting both the heart and lungs. There is more or less oppression in breathing, amounting sometimes to orthopnea and threatened suffocation. It appears almost immediately after eating and ceases when the process of digestion is completed, coming on again after the next repast. The cardiac troubles consist in dilatation of the right side, secondary tricuspid insufficiency sometimes following. There is a *bruit de galop*, which has its seat in the right heart, and also an accentuation of the diastolic sound at the level of the pulmonary artery, indicative of increased tension in the lesser circulation. During the attacks of dyspnea there are observed a small, soft, and compressible pulse, cyanosis, coldness of the face and extremities, and sometimes even slight hæmoptysis. C. The symptoms arranged under the third group resemble very closely angina pectoris. D. In the last form the phe-

nomena are scarcely noticeable; there is a little oppression in breathing after meals, and examination reveals a slight accentuation of the second sound at the pulmonary orifice, but there is no trace of dilatation of the heart. These varieties may be entirely distinct or there may be a combination of the symptoms of several forms. 2. These different phenomena are the consequence of a reflex action starting from the seat of digestive disturbance. The pulmonary capillaries are thrown into a state of spasmodic contraction, causing suddenly an exaggerated tension of the pulmonary system, and the right heart, struggling against this obstruction ahead, becomes first dilated and then hypertrophied. 3. Experimental physiology has demonstrated that this reflex action takes place wholly in the sympathetic system; nevertheless, clinical observation permits one to believe that the pneumogastric nerve is not entirely unconcerned in the production of these reflex symptoms. 4. These cardiac and pulmonary phenomena are observed to occur only with the milder dyspeptic troubles, and are never met with in the course of the more serious affections involving tissue changes (chronic inflammation, organic degeneration, etc.). 5. The above-described symptoms are met with usually in individuals whose nervous system is most impressionable. Women are more often affected than men (in the proportion of three to two according to the author's observations). Chlorosis and hysteria are predisposing causes. 6. The dyspeptic conditions giving occasion to these cardio-pulmonary symptoms are, as regards the stomach, simple idiopathic catarrh, and dyspepsia consequent upon tuberculosis, kidney disease, uterine affections, and heart disease; as regards the bile-ducts, catarrhal jaundice, biliary calculi, etc. 7. The prognosis, as a rule, is not grave, but the phenomena are subject to a recurrence in persons who are careless on the subject of alimentary hygiene. When the primary cause persists for a long enough time (as, for example, in impaction of a calculus in the bile-duct) and the dilatation of the heart is extreme, tricuspid insufficiency may be produced, and the patient may finally succumb to cardiac disease. 8. An exclusively milk diet is the only efficacious remedy. It works wonderfully well in gastric dyspepsia, but its action is indifferent and inconstant when the liver is the cause of the digestive troubles.—*Journal de Médecine de Paris*, June 9, 1883.

THE BILIARY CAPILLARIES.—The precise histological structure of the capillary network of bile-ducts in the lobules of the liver has not been satisfactorily settled. Is there a special epithelioid lining to these minute channels or not? M. Kanellis has communicated to the Académie des Sciences a note of some investigations made on the livers of rabbits with the aid of injections of nitrate of silver. The conclusion at which the histologist arrived (*London Lancet*) was to the effect that there does exist a flat, thin, tessellated epithelial lining of the ultimate biliary canaliculi, and that the larger ducts possess a coat of prismatic cells. This observation is believed to afford grounds for a belief in the existence of a distinction between the biliary and glycogenic functions of the liver; the epithelium of the biliary channels presiding over the functions of bile secretion, while the hepatic cells proper are devoted to the formation of glycogen. When the small size of the intralobular biliary capillaries is borne in mind, the determination of the presence or absence of a special epithelial lining, even with the aid of injections of argentic nitrate, will certainly not seem to be an easy matter, especially when we remember that an inference in histology is seldom or never a matter of direct observation. The distance, too, between such cells of doubtful existence and the genuine hepatic tissue is so infinitesimal that the relegation of one function to one structure must be an act of discrimination of so delicate a nature that we do not think much weight ought to be attached to the suggestion offered.

THE CAUSATION OF MUSICAL CARDIAC MURMURS.—As a result of observations extending over a considerable period of time, Professor Schrötter communicated to the Vienna Medical Society (*Allgem. Wien. Med. Zeit.*, No. 1, 1883), his views on the causation of musical murmurs heard over various parts of the heart's area. Following Hamernik, he regarded the fine, musical, high-pitched note sometimes observed over the left ventricle as due to the abnormal tension of one or more chordæ tendinæ, and demonstrated in illustration thereof the heart of a man of forty, in which a fine, tendinous thread traversed the cavity of the left ventricle. In some other cases, however, viz., those of musical murmurs heard over the aortic area, similar conditions have been observed, especially in perforated aortic valves, a thin, tendinous thread corresponding to the free edge of the valve being left free to vibrate in the current of blood. Such perforated valves are not uncommon, but it is only in the cases where the thread-like margin is able to be vibrated that the musical sound is produced.

TEST FOR IODINE IN THE SYSTEM.—Dr. Starke makes use of the following test to ascertain whether his patients have followed his directions when he prescribes iodides. It might also be made use of by a physician to learn whether a patient has taken iodides against his wish. He lets the patient spit on a strip of white paper and then spreads some calomel over it, or he sprinkles calomel on any sores that the patient may have. The calomel turns bright yellow if there is any iodine in the system.

CALOMEL AND MICRO-ORGANISMS.—Dr. Vassilieff has published some interesting researches concerning the action of calomel on the contents of the intestines (*Zeitschr. für Physiol. Chemie*). He alleges that he has proved that this drug leaves the gastric, hepatic, and pancreatic secretions absolutely unchanged. But it prevents certain processes of retrogressive metamorphosis and putrefaction, by destroying bacteria and micrococci naturally present in the alimentary canal. Hoppe-Seyler has rightly attributed the bright green color of calomel stools to the presence of unaltered bile in the feces. Under normal conditions the coloring matter of bile is destroyed in the process of digestion. But Dr. Vassilieff argues that calomel prevents this destruction, and the coloring material remains to give to the feces their peculiar hue under these conditions. The pancreatic secretion is peculiarly complicated, and particularly liable to very rapid decomposition, with the consequent formation of indol and allied products. Calomel entirely prevents this change, and also alters the characters of the gases evolved in the process of pancreatic digestion, especially diminishing the evolution of carbonic acid. Experiments on artificial pancreatic digestion proved that, when calomel was mixed with pancreatic juice, proteids, starch, and fats were all acted upon in the usual manner, trypsin, amylase, and steapsin being unaffected by the drug, but indol, long recognized as a product of decomposition, is not formed. Dr. Vassilieff, in a further series of experiments, found that this prevention of decomposition was due to the distinctly aseptic and antiseptic properties with which calomel is endowed. He discovered that it prevented the formation of bacteria and micrococci in food removed from the intestines and freed from these micro-organisms, and that it also destroyed them where they were present. Dr. Vassilieff administered fifteen grains of calomel to a dog, in two equal doses, and killed the animal a few hours after the second dose. The contents of the intestine were collected and analysed with every precaution. No indol or phenol could be found, but much leucin and tyrosin, generally destroyed at an early stage of digestion, were detected. This experiment appears to have been repeated more than once. Other experiments, with cheese, showed that calomel prevents butyric acid fermentation.

CREDE'S METHOD.—The value of Credé's method of expelling the placenta has recently been tested by comparative trials. Fehling used Credé's method in ninety cases. The placenta was left to come away itself in ninety-five cases. The following were the results: In the first series (Credé's method) the average loss of blood for each patient was five and one-half ounces. The time before the placenta came away averaged 7.7 minutes. In the second series the average loss of blood was six and seven-tenths ounces. The time before expulsion was 13.4 minutes. In eighty-five of the ninety cases treated by Credé's method the membranes came away entire. In ninety-one of the ninety-five cases left alone the membranes came away entire.—*Ohio Medical Journal*.

TREATMENT OF INFANTILE GASTRO-ENTERITIS.—From observations made in the Children's Hospital, at Pesth, Dr. Epstein concludes (*Prager Medic. Wochens.*) that a liquid diet, poor in fatty matters, is the basis of treatment of gastro-enteritis in young infants. He recommends particularly an albuminous lemonade, obtained by beating up the white of an egg with a pint of water, previously boiled, the resulting mixture being then carefully filtered. At the Pesth hospital this is prepared fresh three times daily, and is kept in a bottle well corked and placed on ice. In a word, all precautions are taken to prevent the introduction of micro-organisms into the system. Nursing from the breast should be completely stopped for the first few days. Every three hours two ounces of milk at a lukewarm temperature may be given to the child, either with the bottle or by spoonfuls. The child should not be put back to the breast until the loss of flesh, which is considerable at first, commences to diminish. Again, when at the commencement there is violent vomiting and rejection of yellowish curds, Epstein washes out the stomach daily, for from eight to fifteen days, by means of the œsophageal tube. As regards direct remedial measures he employs the following potion:

R. Sodæ et magnes. benzoat. ʒiv.
 Sp. vini gall. ʒss.
 Aquæ ʒvj.
 M. Sig.—Teaspoonful every two hours.

CONGENITAL DIVERTICULUM OF THE LEFT VENTRICLE.—A rare and curious example of cardiac abnormality has been recorded by Dr. Gibert (*Le Progrès Médical*, June 9, 1883) as occurring in an infant who lived to the age of ten months. The child was born with a ventral hernia, the abdominal wall being defective in the middle line from the umbilicus upward. A large pulsating vessel was noticed to be present together with the hernia, and as time went on this vessel increased in size till at the time of death it was as large as the finger. On examination it was found that the diaphragm was also defective, so that the pericardium opened into the peritoneal cavity, and projecting into the abdomen was a pouch-like diverticulum, connected with the apex of the left ventricle, with muscular walls, and internally marked by fleshy columns like the ventricular cavity itself. This diverticulum was thirty-eight millimetres in length, and shaped like the finger of a glove. Dr. Gibert suggested that the non-closure of the ventral wall was probably due to the presence of this cardiac deformity. But the converse hypothesis, that the pouching of the ventricle depended on the defect of the diaphragm and abdominal wall, seems to be held by Dr. Blanchard, who made a further dissection of the specimen, for he speaks of it as being the congenital formation of a kind of true infundibular form of aneurism of the apex of the left ventricle—a fact the more curious, because at that period of life the left ventricle only plays a very subordinate part, and this protrusion of a portion of its wall cannot therefore be attributed to an excess of internal pressure. However, we are not aware that in any recorded case of pericardial deficiency a similar ventricular

aneurism has been observed. Dr. Peacock, who refers to several cases of defect of the pericardium, including the classical one referred to by Baillie, makes no mention of such an abnormality in his work on "Malformations of the Heart."

GRUBS IN THE INTESTINES.—No insect, properly so-called, has ever been proved to take up a permanent abode in the human alimentary canal. Their presence, when they were found, was accidental, as when swallowed on a piece of meat upon which the eggs had been deposited. But occasionally larvæ may give trouble. Dr. Wacker (*Med. and Surg. Reporter*) has published the case of a boy, aged twenty-one, with colicky pains, fullness in epigastrium, constipation, and frequent fits of nausea and tendency to syncope, especially when in a close atmosphere, such as that of his cottage or a stable. Dr. Wacker prescribed some Hunyadi János water, to be taken every morning on an empty stomach. On the third day a vast mass (over two litres) of larvæ, partly alive and partly dead, was passed from the rectum. The patient at once recovered, feeling no more unpleasant symptoms, even when in a hot room. On examination, the grubs were found to be larvæ of a common dipterous insect, *anthomyia cuniculinæ*, closely allied to the house-fly and blue-bottle fly.

VESSELS AND NERVES.—The nervous system dominates not only the physiology but also the pathology of the highest animal organisms. This fact is a corollary to at least two important principles—the indivisibility of physiology and pathology, and the supreme importance of the neural tissue in all the superior classes of animals. The truth and the value of these considerations can receive no better illustration than the all-powerful influence of the neural apparatus in the production of disease of the various tissues. A careful and valuable series of experimental researches on the influence of the nervous system in the causation of disease of the vessels has been contributed to a recent number of Virchow's *Archiv* by Dr. Lewaschew, of St. Petersburg. The conclusions at which this experimenter arrives are definite, and correspondingly easy of comprehension, especially in the light of what we already know concerning the origin of tissue changes as the result of neurotic lesions. The method of investigation is worthy of mention. Generally the chief nerve-trunks of the hinder extremities of dogs were the parts subjected to irritation by means of a solution of muriatic or sulphuric acid. It was found that rabbits and cats were unfit for this continuous form of stimulation, because the action of the acid on the exposed nerve-trunk brought about gangrene and, as a strong stimulus was wanted, milder means could not be employed. The observer then noted chiefly the vaso-motor changes which ensued. But the most important part of the research consisted in the examination of the various vessels which received their nerve supply from branches of the irritated nerve-trunk. The most satisfactory results were obtained from the sections hardened in picric acid and stained with logwood. The alterations were most advanced in the smaller vessels—in those provided with a good coat of muscular tissue. The duration of the constant irritation was variable, some animals being examined, after a few months, whilst others lived for a year and a half or more. The microscopical examination of the vessels of the limb experimented on was compared with that of those of the other limb, which had been under precisely the same conditions, with the exception of the special form of irritation. No change was detected in the unirritated limb. It must first be mentioned that the pathological changes found in the vessels of the limb operated upon were not equally distributed over all parts of the vessel, but the areas of disease, of varying size, were separated by areas of sound tissue. The investigation of the arteries of animals in which the sciatic nerve had been stimulated a moderately short time, or in the least affected vessels of those animals in which the stim-

ulation had endured for a lengthened period, resulted in the detection of alterations chiefly of the adventitious coat. New formation of vessels, with the presence around them of a great number of indifferent cells, was observed; and this process was seen to extend itself more or less into the muscular tissue, whereby the bundles of plain muscular tissue were separated from one another. In vessels which had been irritated for much longer periods, a development of connective tissue which had undergone fibrillation and had displaced and destroyed the middle coat was witnessed. In brief, the changes detected were those of periarteritis, mesarteritis, and endarteritis, in the order here mentioned. Such inflammatory alterations are of great importance in the production of aneurisms, and the bearing of these recent experiments on vascular pathology is too evident to need a long description. The ascertained relation between the pathological processes in nerves and the diseases of the vessels suggests an explanation of the frequent disease of the cerebral vessels. The similarity of the lesions described above to those which have been delineated by various histologists need not lead to the conclusion that *all* fibroid vascular diseases are the result of nerve irritation; it must ever be borne in mind that a variety of causes may produce identical results.—*The Lancet*.

A THREE-BARRELLED PENIS.—Dr. Luxardo describes a rare anomaly of the penis which he observed in a young man under treatment for gonorrhœa. The meatus presented three openings, which corresponded to as many distinct urethral canals. The upper one gave passage exclusively to seminal fluid, the lower one to urine. The middle tube appeared to communicate with the lower one. The gonorrhœa affected only the two inferior canals.—*L'Union Médicale*, No. 54, 1883.

A CASE OF PRIMARY MONOMANIA.—The circumstances connected with the trial of Guiteau brought prominently to notice a peculiar form of insanity, the so called primary monomania. In view of the professional interest attaching to this variety of mental disease, the publication of the case reported by Dr. C. B. Burr, of the Eastern Michigan Asylum, in the July issue of the *American Journal of the Medical Sciences*, is timely, and attracts attention on account of the resemblance it bears to that of Guiteau. Disregarding the moral traits of these two individuals, their cases are strikingly similar. In contradiction of the oft-repeated assertion that the execution of an insane criminal now and then has a deterrent effect upon others of like propensities, Dr. Burr's case may well be cited, inasmuch as his homicidal assault was made less than five months after the hanging of the murderer of the President, and in face of the strong popular sentiment against the so-called "cranks" and lawless fanatics. There are few more striking illustrations of the impotency of moral and legal measures to restrain or control a morbid impulse than is afforded by this case.

A CASE OF CARDIAC ANOMALY.—Dr. Horace Grant, of Louisville, reports in the July number of the *American Journal of the Medical Sciences* a remarkable anomaly of the human heart, interesting not alone from its striking singularity, but as well from its clinical importance. In a post-mortem examination of a mulatto girl, sixteen years of age, the right ventricle was found to communicate directly with the aorta; no pulmonary artery was to be seen attached to the heart. The left auricle was normal; the left ventricle presented only one-half the usual attachment of the aorta. In a word, both ventricles opened with equal freedom into the aorta. At the pericardial attachment to the aorta two arteries were given off, each about one-fourth of an inch in diameter; they passed right and left backward from the front of the aorta, and evidently supplied the blood to the lungs. This curious anomaly is discussed in connection with the clinical symptoms observed during life.

Reviews and Notices.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE THROAT, NOSE, AND NASO-PHARYNX. By CARL SEILER, M.D., Lecturer on Laryngoscopy, at the University of Pennsylvania, etc., etc. Second Edition, thoroughly revised and greatly enlarged. With seventy-seven Illustrations. Small octavo, pp. 295. Philadelphia: Henry C. Lea's Son & Co. 1883.

THIS edition is twice as large as the first, containing new methods and much original matter. While making extensive additions to the wood-cuts, it would have improved the work to have omitted more of the old ones. The position of the mirror shown in Fig. 3, resting high upon the forehead, instead of a perforated reflector over the eye, is probably an oversight or a relic of the author's abandoned methods, since it is entirely at variance with laryngoscopy as now practised. The author's ingenious utilization of electrical incandescence for laryngoscopy and rhinoscopy has paralleled if not preceded the invention of a somewhat similar instrument by the French electrician, Trouvé. His convenient disposal of the various forms of laryngeal paralysis by employing the frequent symptom "aphonia" is hardly justifiable. Even a division of paralyses constructed upon modified symptoms, as aphonia, dysphonia, and altered voice, must prove inferior to one based upon motion. Attention is attracted to an original anatomical feature in the larynx, a cartilage described as running along the edge of the cord on a line with the processus vocalis. It only occurs in the female, and we fail to find it mentioned in the literature of the subject. The anæsthetic effect of nitrate of silver applied in full strength to mucous membranes is a therapeutical point first discovered by the writer. There are several wood-cuts of instruments shown for the first time in book-print. Among them we observe the Burgess blow-pipe, recommended for the practice of atomization, also a very useful automatic hydraulic air compressor.

We do not agree with the author in taking exception to text-books which refuse to recognize the existence of ulcers due to catarrhal changes in epithelia. His explanation of hypertrophic changes in chronic coryza, produced in part by catarrhal proliferation of cells, does not completely harmonize with this statement. Undoubtedly, the abrasion caused by the constant removal of adherent inspissated mucus may result in perforation of the nasal septum. This passive condition is, accurately speaking, no more an ulcer than the erosion caused and kept up by the pressure of a markedly deviated septum. The chapter on "catching cold" is a well-arranged and ingenious explanation of this common phenomenon. Decided preference should be given to the section devoted to diseases of the nose. New and original ideas are constantly presented to the reader, and the matter is conveniently and attractively arranged. Nasal medication receives ample attention, the surgical treatment of diseases of the nose being more fully considered on account of the positive result obtained. A galvano-cautery apparatus, convertible at pleasure into a galvanic or faradic battery, is probably the most interesting of the author's inventions.

Among the illustrations is a powerful sewing-machine electric motor, recommended as a convenient substitute for the surgical engine. Jarvis' operations are advocated by the author. Some of the new wood-cuts representing hypertrophic changes in the nares seem to have originated more in the draughtman's memory than from clinical experience, judging from the appearance of Figs. 49, 56, and 57. A number of the wood-cuts, however, are well and correctly executed. Taken in its entirety, the work may be considered as one of the most satisfactory and complete manuals on this subject. There is abundant evidence that it is not an effort of mere compilation, but also the result of original thought and careful investiga-

tion. The faults of omission and commission are not numerous or serious, and are more than counterbalanced by the merits of the work. The simplicity of the style and freedom from technicalities recommend the book to the beginner, and the valuable information, representing the experience of a well-known authority on diseases of the throat, makes it a desirable addition to the library of the advanced reader.

HANDBOOK OF ELECTRO-THERAPEUTICS. By DR. WILHELM ERB. Translated by L. PUTZEL, M.D. With thirty-nine Wood-cuts. New York: William Wood & Co. 1883. Wood's Library of Standard Medical Authors.

THE publishers have done a good service by presenting a translation of this book to American readers, since it is probably the best work on the subject of electro-therapeutics, considered especially from a scientific standpoint, yet published. A certain amount of humbug has always surrounded the therapeutic application of electricity, and it is refreshing to find an author who endeavors to measure everything as much as possible by physical and physiological law. Very nearly one-half of the present work is devoted to electro-physics, electro-physiology, electro-diagnosis, and general electro-therapeutics. These parts are particularly good. Few practitioners yet appreciate the value of electricity as a help to diagnosis and prognosis; and no doubt Erb's work will do something to call the matter to their attention.

Some of the principal things which the author insists upon are the use of galvanometers, of large electrodes, and of the polar method. Under special electro-therapeutics the author tries evidently to give a fair estimate of the value of electricity in each disease. Every electro-therapist, however, when he becomes a writer, is apt to become biased in favor of the potent agent concerning which he discourses. Erb has not entirely escaped this fault. Furthermore, we might complain at his too ready acceptance of cases reported by such quasi-authorities as Nefel, Benedikt, and Clemens.

A TREATISE ON INSANITY IN ITS MEDICAL RELATIONS. By WILLIAM A. HAMMOND, M.D. New York: D. Appleton & Co. 1883.

THE appearance of numerous works upon insanity during the last two or three years is a striking evidence of the increased interest everywhere taken in this subject. The works of Voisin and Luys in France, of Krafft, Ebring and Arndt in Germany, as well as of three treatises published almost simultaneously in America, are sufficient proofs of the fact referred to. The present work of Dr. Hammond's is likely to attract particular attention, both because of its being the first American work upon insanity, and of the well-known ability of its author. Dr. Hammond has the faculty of presenting every subject which he touches in a clear, interesting, and positive manner, so that the reader can hardly fail to be impressed, and (at least if non-expert) to be decidedly affected by his views.

In the preface of his work the author states the opinion which he has expressed with much positiveness before, that the ordinary conception of insanity is much too narrow, that a slight mental aberration is as truly insanity as is acute mania. Many persons, however, with but slightly unhealthy minds are, he believes, responsible. He would, therefore, make a division practically between "medical" insanity and legal insanity. The point thus made is a most important one.

It may be remarked, however, that the attempt to include under the technical term "insanity" all individuals whose minds deviate markedly from the normal, would oblige us to include nearly all constitutional criminals and a vast number of persons with inherited or acquired neuropathic constitutions, the "cranks," the markedly eccentric and the moral imbeciles, e.g., Pascal, Samuel Johnson, Henry Bergh, and Dr. Tanner. We would be deluged indeed with this medical insanity. It may be

questioned, therefore, whether it would not be better to give to this class another name, indicating that their mental impairment is differently accentuated. Yet, after all, the question is not of fundamental importance. In time, society will learn to treat all bad and all eccentric men, as well as all insane men, as really sick men.

Dr. Hammond begins his treatise with a section on the Physiology and Pathology of the Human Mind. His psychology is of the simplest kind. This is a merit which few others have attained, and it is attained at the expense of some inaccuracies. The mind, says our author, is a compound force, made up of perceptions, intellect, emotions, and will. We confess that this simple analysis disturbs our previous psychological views a good deal. Perception, according to the author, is the force which places the individual in relation with external objects. Its seat is thought to be in the optic thalamus. It is the starting-point of ideation; it is not inherently associated with consciousness.

It is evident that the writer has confused the terms perception and sensation; and we think that mental process can be explained without the use of the latter term. Indeed, of the two we might better abandon the term "perception," as the elder Mill did.

Sensation is the simplest form of consciousness. A simple sensation is the consciousness of a single sensorial impression. Only brutes and infants have it. Our sensations are generally the compound of a number of sensations—sensation-clusters, so to speak. Perception is the process by which a fresh sensation is united to or correlated with previously registered impressions. By its aid ideas are formed, and ideation and ratiocination take place. Neither perception nor sensation are located in the thalamus, for they are associated with consciousness, though doubtless these ganglia are closely associated with the elaboration of the ingoing impulses which are the raw material of the mental phenomena in question.

The definition of will as a special mental force is perhaps practically necessary, though the tendency at present is to do away with the word and substitute that of "volition," which indicates action rather than special power or choice. There is no such thing as free-will, which, as Arndt says, "is the shibboleth of the ignorant; and a will not free is no will at all." What is known as will is rather the resultant of certain antecedent forces which can not always be analyzed.

We have discussed this part of Dr. Hammond's work at perhaps undue length. We have felt justified however, in so doing, because his psychological divisions are made the basis of his future classification and symptomatology. The fact that they are not rigidly accurate is, therefore, important to point out.

The remainder of the section in question is devoted to such subjects as the Influence of the Mind upon the Body, Eccentricity, Idiosyncrasy, Genius, Habit, Temperament, Constitution, Hereditary Tendency, Age, Sex, Race. Much more space than usual, and perhaps than is needed, is devoted to these various subjects. We confess, however, that we do not ourselves regret it, since they are written in an attractive style and show the results of a most extensive reading, observation, and thought.

The second section contains two chapters upon the Nature and Seat of Instinct. The discussion of the nature of instinct contains a good many quotations which are interesting but inconsequential. The author's own definition and view are unquestionably correct. His attempt to locate instinct in man in a particular part of the nervous centres can hardly be considered successful. Instinct is the expression of a nervous mechanism whose paths and centres are probably extensive, and not to be definitely circumscribed. We might make the same criticism of the section upon Sleep, viz., that it is an unnecessarily long, though an instructive one. We are surprised not to find among the numerous au-

thorities quoted the name of Preyer. While the author has undoubtedly established the fact that in sleep there is a cerebral anæmia, he strangely enough still insists that this anæmia is the primary cause of the condition. The blood-vessels, however, are the servants of the nervous system and cannot decrease in calibre except at its bidding.

The last section is upon the Description and Treatment of Insanity. We find that before reaching it we have already exceeded our allotted space. We can only say now, therefore, that though much elaborated and improved it is based mainly upon the chapter on insanity in the author's work on "Nervous Diseases" (earlier editions). There is no doubt that, whatever its deficiencies, it will give the general practitioner a clearer idea of insanity than he can get from any other text-book in the English language.

We can, on the whole, heartily commend Dr. Hammond's book to our readers. While the author is not a trustworthy guide in all the subjects upon which he touches, yet his errors are not dangerous, and the book in its entirety is so broad in scope and so rich in material that it will be an education for the physician who reads it.

INSANITY: ITS CAUSES AND PREVENTION. By HENRY PUTNAM STEARNS, M.D. Pp. 248. New York: G. P. Putnam's Sons. 1883.

This work is not a scientific treatise intended for physicians alone, but is rather a contribution to a most important branch of sociology. It consists of a series of essays upon the nature of insanity, the various factors which produce it, and finally upon its prevention. The essays are pleasantly written, and contain in some instances evidences of considerable research. In most cases, however, the chapters are simply the impressions and opinions of a man of wide experience, rather than the results of special study and investigation. The tone of the book is throughout healthful and sensible, and we should be very glad to know that the work is widely read, for it certainly deserves to be.

LA CIRCULATION DU SANG. Examen critique de la Théorie Régnante. Sur le Mouvement Circulatoire du Sang, et Essai sur la Théorie par laquelle on doit la remplacer. Par le DR. RAMON TURRO. Traduit de l'espagnol par JULES ROBERT. Paris: O. Berthier. 1883.

The author endeavors to prove that the arterial walls have an independent rhythmical contraction which assists in the propulsion of the blood.

A HISTORY OF TUBERCULOSIS, FROM THE TIME OF SYLVIVS TO THE PRESENT DAY. By DR. ARNOLD SPINA, First Assistant in the Laboratory of Professor Stucker, Vienna. Translated, with Notes and Additions, by Eric E. Sattler, M.D. Cincinnati, O.: Robert Clark & Co. 1883.

The publishers state that the first five chapters of this book are a free translation, with a few notes and additions, of the first of the very valuable work of Dr. Arnold Spina, which has just appeared in Germany. Every careful medical reader of to-day knows that Spina is the most formidable critic and opponent of the theory advanced by Koch concerning the Tubercle Bacillus. To these chapters Dr. Sattler has added two which contain an account of the investigations of Koch and of the various subsequent experiments of other investigators; also a full description of the latest experiments of Dr. Spina, in which he claims to have disproved Koch's theories, together with Koch's reply. The book, therefore, gives the position of the combatants down to March, 1883, and is a monograph of 184 pages, well printed upon good paper. It is one of the most concise *résumés* of what has been said concerning the pathological anatomy and histology of tuberculosis.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 28, 1883, to August 4, 1883.

TURRILL, H. S., Major and Assistant Surgeon. Granted leave of absence for one month, to commence September 1, 1883. S. O. 77, Department of the Platte, July 26, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending August 4, 1883.

COLES, J. W., Surgeon, ordered to the Naval Hospital, Philadelphia, Pa.

MARSTELLER, E. H., Passed Assistant Surgeon, detached from the U. S. S. Hartford and granted sick-leave.

BRANSFORD, J. F., Passed Assistant Surgeon, detached from the Naval Academy and ordered to the Hartford.

BOGERT, E. S., Medical Inspector, detached from the Navy Yard, Norfolk, on August 30th, and ordered to the U. S. S. Trenton, September 1st.

TIREBEE, N. MCP., Passed Assistant Surgeon, detached from the Navy Yard, Norfolk, on August 30th, and ordered to the U. S. S. Trenton, September 1st.

GATEWOOD, J. D., Passed Assistant Surgeon, ordered to the Trenton, September 1st.

KIDDER, B. H., Surgeon, detached from the Naval Station, Port Royal, and ordered to the Navy Yard, Norfolk, August 30th.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 7, 1883 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

HOW, IN A CROWDED PROFESSION, BANGS GOT A START.—The little village of Millbrook was disturbed in its calm serenity by the advent of two new doctors. Now there will be more sickness, people said, for so many doctors must find work to do. From time immemorial Millbrook had never had so many physicians before. Not that three medical men might not be well supported, for Millbrook and vicinity numbered twenty-one hundred inhabitants; and is it not a (social) law of nature that every seven hundred people must support one doctor? Four doctors, however, were one too many, and only the strongest and fittest would survive in the struggle for existence.

Brown and Bangs were the new-comers: Brown from the important medical college of Grande Montagne; Bangs from the little *one-horse-power* concern of Camperdown. Brown had the most titles. He was an A.B. and an U.D.M.C., the last two letters meaning master of surgery. Bangs had done no good work at college,

but had somehow managed to get through with a diploma in classic sheepskin, and in Latin, signed by ten professors, which hung in his office in an elegant frame. Brown's friends said that Bangs could never succeed, for in medicine, as in *Sabbath-school library books*, it is always the good boy and good student that is rewarded, while the bad boy that shirks his lessons and "slopes" examinations comes to grief. Besides, Bangs' diploma, coming from *such* a school, would be no help to him, while Brown's Grande Montagne diploma would powerfully recommend him to favor. So Brown's friends thought, and so it seemed to Brown. Moreover, it was known to a few that Brown had written a prize thesis of great merit on "Pityriasis Versicolor," which contained some original drawings, and in which the parasitic origin of this cutaneous affection was ably maintained. He had also made some personal investigations, while a hospital interne, of that curious insect the sarcoptes hominis, in which the habits and habitats of the parasite were well described. As a therapeutic measure he had proposed the ingenious plan adopted by hunters in the case of wolves, of smoking the little animal out of his haunts by the fumes of burning brimstone applied to the orifice of entrance. There was, however, nothing especially new in this medication (as was very properly pointed out by the faculty), sulphur having been for more than a hundred and fifty years, from empirical considerations, employed against this common pest of mankind. Brown was well grounded in the general principles of therapeutics, but he had not yet learned that while sound theories are very necessary in applying them to practice, you have the whims and caprices of the patient to contend against, and that you never really have *diseases* to treat, but only *sick people*. Symptom-treating, he believed, was irrational; you must seek out the diathesis, and "go for" it; find the point of departure of the morbid phenomena, and attack it, rather than the symptoms, which would disappear with the disappearance of their cause. This is very good theory, but is not to be followed too rigidly. If Bangs had any theory of therapeutics, it was that symptoms are the key to disease, and the physician's highest art is to attend to and treat symptoms. A furred tongue generally requires an evacuant; pain calls for an anodyne; diarrhoea a corrective or an astringent. Bangs had pored earnestly over certain treatises on "Specific Medication," believed a thousand or more improved and very doubtful statements contained in them, and thought himself on the path of progress.

Brown believed that his services would be in demand, and that he might "select" his patients and patrons. Bangs was willing to take "anything and everything that came along," and improve every opportunity to "rush in where angels might fear to tread." It was a boldness and an impudence that very often in this misconstrued world give success. To cut short our tale, Brown did not obtain a foothold in Millbrook, and left discouraged in less than six months. Yet he might have succeeded but for two circumstances. Do you wish to know what these were?

He had not been in Millbrook many weeks when, one stormy evening, late in autumn, a messenger came in hot haste for a physician—one of the Wilsons, of Dogtown, ten miles distant. The weather was cold, and the road very muddy. There was a sick child in Dogtown, and the case was urgent. Dr. Grimes would not go on account of the roads, and Clay, the homœopath, had declined for the same reason. Brown, too, declined, when he was informed that the pay was doubtful. He would not expose himself to such inclement weather "with an uncertainty before him." Here he made a grave mistake, as we shall see. Bangs was summoned, and in five minutes time was ready, equipped, and in his saddle. In one hour and ten minutes he had gained the cottage of his patient. It was a case of typhoid fever, and the sick girl had been suffering from a prolonged

attack of epistaxis. Bangs plugged the nostrils (he fortunately had a flexible catheter in his pocket) and stopped the hemorrhage. He came the next day and the next, and so on, and the little patient eventually recovered. His brilliant surgical operation of tamponing the nostrils (which had never before been performed in that part of the country) gave him great repute in Dogtown, and henceforth he could claim all the families of that rural district as his. This was an excellent start for Bangs, and one that he well improved. The fever proved epidemic in Dogtown, and that very year Bangs scored one hundred and fifty visits to that distant agricultural settlement. This professional work, at three dollars a visit, gave his small family for a long time a comfortable support.

"Aunt Jane Hopkins," as she was familiarly called, was a spinster of large influence in Millbrook. Brown, who early in his professional career had been honored by being consulted by this mistress of gossip, had severely offended her by making light of the back-ache, the side-ache, and a host of neuropathic troubles. He had recommended a diet treatment for her dyspepsia, when Aunt Jane knew that she needed medicine. He had even called her neurasthenic ailments *hysteriform*! and had counselled greater firmness of will.

Aunt Jane gave him up in disgust, and called in Bangs. Here was just the man who could enter into sympathy with her infirmities, and who had a specific for every symptom. She was "doctored" for "womb trouble," and "spinal irritation," and "dyspepsia," and "liver complaint," and finally got well after taking six different kinds of medicine daily for eight weeks! Henceforth Aunt Jane acted as though her principal mission in life was to sound the praises of her favorite physician. Those who know anything about the elements that usually constitute village society, can well appreciate the benefit that Bangs derived from such persistent advertising among the gossips of Millbrook.

In short, Bangs' bread was soon "battered on both sides," and Brown, as before said, left discouraged.

INDICATIONS AND CONTRA-INDICATIONS FOR THE USE OF DIGITALIS IN MENTAL DISEASES.—Dr. Pedro Ribas, in an article published in the *Revista frenopática Barcelonesa*, gives the following as the indications and contra-indications for the use of digitalis in mental diseases:

Indications.—1. In acute mania with anæmia, dilated pupil and feeble heart-beat. 2. In chronic mania of tranquil form, especially in those cases characterized by hallucinations of sight and hearing. 3. In hypochondriacal mania, especially where thoracic and pulmonary troubles are complained of. 4. In suicidal mania and melancholia. 5. In religious ecstasy and fear. 6. In the melancholy and depressive stage of general paralysis, especially if anæmia be present. 7. In simple, primary dementia.

Contra-indications.—1. In acute, violent mania. 2. In simple, chronic melancholia. 3. In cataleptic ecstasy. 4. In most forms of general paralysis.

Dr. Ribas, as will be seen, draws some fine distinctions. —*El Siglo Medico*, April 1, 1883.

THE DIFFERENT KINDS OF QUACKS.—According to the *Gazette Hebdomadaire* the genus of the quack varies in France with his nationality. It may be interesting to know that the American quack, as he flourisheth abroad, is "high in color, loud in voice, noisy and impudent." That is the rôle he usually plays also in this country, but he does not confine himself to it. In his great versatility he adapts himself to the peculiarities of his dupes. We have seen him pale, of smooth and delicately modulated voice and exceedingly demure. The Spanish quack abroad is, we are told, "mystic, sombre, the crucifix in hand, always ready in prayer." That lay has not been worked here to any great extent, and it might be made to pay. "The Dutch impostor, writing his consultation

with a flask of urine in hand, as in the famous 'Dropsical Woman' of Gerard Dow," would scarcely be adapted to the genius of this country. There are some, however, who are favorably impressed through the urine. But the kind which carries the palm abroad, and is the peculiar abomination of the French profession, is the German quack, "surrounded with piles and electric apparatus; a professor of occult physical science; who cures with the same spark pulmonary tuberculosis and cerebral debility; a distinguished lecturer and the apostle of a newly discovered art." The latter quack should emigrate. Untold wealth awaits him here. The arrant, blatant, ignorant quack is beginning to lose his grip as our people grow more intelligent, and the "occult" would catch them. They have much more faith in the incomprehensible than they have in that which is reasonable. The theological quack has cultivated this weakness very successfully, and there is no reason why the medical quack should not find it profitable.

THE ACTION AND THERAPEUTIC USES OF ACONITINE.—Laborde has an elaborate article upon the above subject. His experience with aconitine in neuralgia is favorable but not many cases are cited. —*Journ. de Therapeut.*, May 25, 1883.

NAPELLINE AS A SUBSTITUTE FOR MORPHINE.—Napelline, an amorphous alkaloid obtained from aconite root, has been successfully used by Laborde to relieve neuralgia pains, and as a substitute for morphine in a case of the morphine habit. It was given hypodermically in doses of from one to four centigrammes in the twenty-four hours. —*Journ. de Therapeut.*

THE VALUE OF COLOR AND OF MUSIC IN THE TREATMENT OF THE INSANE.—Dr. H. Sutherland refers to Tonga's suggestion that different colors may be used advantageously in the treatment of the insane, and to Dr. Clay Shaw's view that music might also be utilized in the therapeutics of mental disease. He says: In my own experience, the efficacy of such therapeutic agents has been found to depend upon the previous education of the patient and the various crises of his disorder; a change to a more cheerful room, associated with pleasant reminiscences, often exercising a marked influence for the better on the course of the mental disorder. —*British Med. Journ.*, May 5, 1883.

THE THERAPEUTIC VALUE OF THE WATER OF LOURDES.—Drs. Labadie, Lagrave, and Dérignac, give an interesting account of a patient, a woman aged forty-five, not neuropathic, who suffered from a double otorrhea, followed by symptoms of meningitis, epileptiform attacks, contractures, paralyzes, atrophy, mental and sensory disturbances. She was treated for meningitis without success. After being in the hospital for nine months, she went to Lourdes and was immediately cured *secundum artem*. The case illustrates the diagnostic value of faith-cures. —*Archives de Neurologie*, May, 1883.

THE TREATMENT OF THE FILTHY INSANE.—Schüle discusses the measures best adapted to preventing and remedying the filthy practices and habits among the insane. It is very necessary to break up these habits and secure cleanliness whenever possible. Moral treatment, special appliances in the way of beds, hydrotherapy, faradization, coercion in some cases, are the measures recommended. The use of sedatives, medicinal and mechanical tonics, are generally indicated. Non-restraint should not be carried too far. —*Allg. Zeitschr. f. Psych. u. Psych.-Gerichtl. Medic.*, xxxvii., 6.

HYPODERMIC INJECTION OF COLD WATER IN SCIATICA.—Dr. Pollak has communicated to the St. Louis Medical Society a case of sciatica, in which he injected ice-cold water hypodermically deeply into the tissues, with the effect of speedily alleviating the pain. The relief was lasting. —*Philadelphia Medical Reporter*, February 3, 1883.

NERVE-SUTURE.—Johnson cites fifty-two cases of nerve-suture which he has found in literature, to which he adds some cases communicated to him personally. He has performed sixteen experiments in nerve-suture; uniting in these cases the totally dis severed ends of a sciatic nerve with a catgut suture. He recommends nerve suture as deprived of all danger. In fifty-two cases of the operation in man there was no bad result, and nervous conduction was established with comparative rapidity. Indirect suture is preferable to direct. Kaufmann, in 1880, successfully transplanted a dog's sciatic nerve in the human being, and from experimental results Dr. Johnson believes that this example should be followed in cases where indicated. He leaves to future experimenters to determine whether nervous conduction is established most promptly and thoroughly by suture, or, as was proposed by Vanlair, by placing between the severed ends a tube of calcined bone (*Nordiskt Medicin. Archiv, Band xiv., No. 31.*)—*Weekly Medical Review.*

MEDICAL PRACTICE IN PERSIA.—Dr. C. J. Mills, an English physician who has resided for fifteen years in Persia, has recently written an interesting work entitled "The Land of the Lion and the Sun." Some of his medical experiences are given. The author had the privilege of attending Persians in their illness. At first he was astonished at receiving no emoluments, but found out that his servants pocketed his legitimate fees. One day a poor patient sends him some money inclosed in a handsome purse. The doctor returns the money, but keeps the purse. Then a rich man hears of this, pays the doctor in money, and puts it, too, in a handsome bag. The doctor keeps the money, and very much to the disgust of his patient, sends back the purse. A well-to-do baker has a cataract, and our medico cures him and receives about four pounds for his fee. When the Persian regains his sight he insists that he is still blind, worse than ever, demands back the money, and is clamorous for an additional sum for an indemnity. The medico knows him to be a rascal, and suddenly flourishes an amputation-knife before the blind man, who at once runs away as fast as his legs can carry him. Demands were constant for quinine, and the doctor had been particularly instructed to distribute it freely when cases required the febrifuge. But the cry for quinine became so constant that the author was certain that it was obtained under false pretences. Then, as a rule, he administered it in solution, or if his servants wanted it he put it in a dry state in their mouths. Then the cry for quinine diminished. In the case of his servants, it was the legitimate *mokadel*, or perquisites of office they were after. They collected the quinine and sold it.

WHAT THE ABUSE OF MEDICAL CHARITY HAS DONE FOR ENGLISH PHYSICIANS.—A correspondent of the *St. Louis Courier of Medicine*, writing upon the subject of the status of English doctors, says: "The social position of the whole medical profession in England is much lower than it ought to be. The distinctions lavished on other professions are very rarely conferred on medical men; but the profession has itself to thank to a great extent for this difference. The amount of gratuitous work done by the profession in no way raises it in the public esteem. It is well known that it is not performed from motives of charity, but for the position which is gained by being attached to a hospital staff, and the hopes of a good practice ultimately accruing therefrom. This custom of gratuitous services to the hospitals has grown on the profession, and many a young physician and surgeon now is exhausting himself in mind and body by attending patients gratuitously at hospitals whose incomes are in some cases much greater than his own. This injustice the public, as represented by the people who support the hospitals, in nowise wish; they would be quite willing that the first charge on the incomes of the hospitals should be to adequately remunerate the medical men who attend upon the sick. But any

reform in this direction must emanate from the heads of the profession. No profession can be expected to rise in social position when kept in a state of penury; and this poverty-stricken state of the medical profession, as it is in England, is a great deal due to the action of those who hold the highest position in it. They preach to the younger members, who are getting nothing from their hospital appointments, to keep up the dignity of the profession by never taking from a private patient less than their guinea or two guinea fee, when the same patient can see men of the greatest reputation and obtain their advice for the same amount. The senior men with high reputations ought never to take less than five or ten guineas; there would then be a chance of the junior members of the profession sometimes obtaining a patient."

MEDICINE IN JAPAN.—A recently published official report gives the number of physicians who have passed satisfactory examinations in medicine and surgery at 1,625; those who have not undergone such examinations, 769; those who have pursued their profession from the time when there was no system of examination, 30,700; oculists, 502; surgeon-dentists, 124; accoucheurs, 417; bone-setters, 86; licensed apothecaries, 415; those who have been in practice from the time when there were no license regulations, 6,426; government principal hospitals, 3—branches, 19; public principal hospitals, 192—branches, 40; private principal hospitals, 202—branches, 11. It will be seen from the above that by far the larger number of practising physicians are still unlicensed, and probably practise according to the old Chinese system. It must be borne in mind, however, that the regulations requiring physicians to pass an examination in anatomy, physiology, materia medica, pathology, practice of medicine and surgery, and obstetrics, and to take out licenses to practise, only came into vogue a few years since, and did not affect those already in practice for three or four years. Medical schools are now increasing in number, and consequently the number of students educated in Western medical sciences. The last annual report of the Medical Department of the University of Tokio shows the actual number of students as follows: medical students, 169 (course conducted by German professors); those following the same course in the Japanese language, 760; pharmaceutical students, 71; making a total of 1,000. There is one licensed physician to about every 22,000 of population, and one unlicensed to every 1,200; or one physician, licensed or unlicensed, to every 1,109.—*Correspondent of Philadelphia Medical Times.*

THE AIM OF LIBERAL HOMŒOPATHY is well set forth in a recent issue of the *Hahnemannian Monthly*, which says: "A few years ago the editors of the *New York Medical Times* dropped from the title of their journal the distinctive word 'Homœopathic;' now they boldly urge the renunciation of the word as applied to our school of medicine. If we are emancipated from the thralldom of *sect*, we shall not only save our school from imminent dissolution, but shall also become an integral part of the medical profession of the day, honored as true, broad, liberal, progressive physicians. But if we cling to a name which by no means represents the catholicity and spirit of the new school, we are doomed to annihilation; and more, we become the common enemy of all allopaths and also of all progressive homœopaths. The neutral ground upon which a lasting truce is to be consummated is the common acceptance of the dual action of drugs. No one denies that ipecac in one dose will vomit, and in another will allay vomiting; therefore no one will contend with another if only this plain truth is adopted as the universal motto of the medical profession."

TREATMENT OF PAINFUL THROAT.—A correspondent asks what is the best treatment for cases of "sore throat," so called, in which there is much steady pain, some dysphagia, and hardly any signs of congestion or swelling.

THE CORPORA QUADRIGEMINA.

WITH REMARKS CONCERNING THE DIAGNOSIS AND LOCALIZATION OF LESIONS AFFECTING SIGHT.¹

BY AMBROSE L. RANNEY, M.D.,

NEW YORK.

THE aqueduct of Sylvius (*iter e tertio ad quartum ventriculum*) is covered on its superior and dorsal aspect by two pairs of rounded eminences, mainly composed of gray matter, called the corpora or tubercula quadrigenina (the so-called "*nates*" and "*testes cerebri*"). A median groove separates these parts. Anteriorly, a transverse white prominence (the *posterior commissure*) limits this groove; behind, it is continuous with the velum by means of a small median strand of longitudinal fibres, called the *frenulum veli*. The pineal gland which projects backward and downward from the posterior wall of the third ventricle overlaps the anterior portion of this groove, resting between the two upper quadrigeninal bodies (the *nates*). In fishes, reptiles, and birds, these bodies are two in number, and are called the *optic lobes*. They are also hollow in these species. In the human fetus they are developed early, and form a large part of the cerebral mass. The anterior tubercles are darker in color and less prominent than the posterior. Laterally, each tubercle is prolonged upward and forward into a prominent strand of white substance, the brachium or arm of the corresponding tubercle. The *brachia* are to be regarded as fasciculi sent to each tubercle from the cortex cerebri by means of the corona radiata. They may also be considered as affording a communication with the optic thalamus. The *upper or anterior brachium* passes between the inner geniculate body and the posterior extremity of the optic thalamus, or the *pulvinar*, where it may be demonstrated to join one of the roots of the optic tract, of which it really is a continuation. This is more apparent in some animals than in man. The *lower or posterior brachium* loses itself underneath the inner geniculate body, which is situated at the side of the upper end of the crus cerebri.

The *upper quadrigeninal bodies*, or *nates cerebri*, are covered externally with a thin layer of nerve-fibres, called the "*stratum zonale*." This constitutes the only place in the brain where fibres of the first projection system of Meynert are exposed to view upon its exterior. Beneath this may be seen a layer of gray matter, called the "*stratum cinereum*," which is thicker at the prominent part of the tubercle than at its margins, and which contains numerous nerve-cells of small size. Beneath this, again, lies a layer of nerve-fibres which are arranged in longitudinal bundles, the so-called "*stratum opticum*." These fibres are continuous with the upper brachium and the optic tract. Scattered nerve-cells are found between the bundles of which it is composed. Finally, between the stratum opticum and the gray matter which surrounds the aqueduct of Sylvius, a layer of nerve-fibres, derived from the upper fillet or *stratum lemnisci*, may be demonstrated. This layer is thickest at the margins of the tubercle and thinnest at the median line, where a few of

its fibres decussate. This gradual thinning is to be explained by the passage of some of its fibres to the optic layer, and some to the gray matter surrounding the aqueduct of Sylvius (Tartuferi).

The *lower quadrigeninal bodies*, or the *testes cerebri*, are composed almost entirely of gray matter formed of numerous small and some large nerve-cells. A thin layer of the fillet separates the gray nucleus of this body from the gray matter surrounding the aqueduct of Sylvius. A connecting band of gray matter unites the gray nuclei of the two bodies. Transverse fibres of the fillet bind this gray commissural band both superficially and deeply. Those lying superficially are continuous, in part, with the brachium of the lower quadrigeninal body, and in part, also, with the fibres of the lower fillet; the fibres of the lower fillet are described by Meynert as being continuous with the brachium of the opposite side. If this continuity really exists, the communication is probably an indirect one by means of interposed nerve-cells in the gray matter.

The *posterior commissure* of the third ventricle, which lies above the upper end of the aqueduct of Sylvius, seems to be a direct continuation of the commissural fibres of the fillet which have been mentioned. It apparently springs from the tegmentum, and, after decussating, appears to traverse the substance of the thalamus, and then to radiate in the white substance of the hemisphere of the cerebrum. A few of its fibres are connected with the pineal gland; some also probably act as commissural fibres between the thalami.

This hasty and somewhat imperfect *résumé* of the anatomy of these bodies will enable us to intelligently consider some of the views which have been advanced respecting their probable functions, and the effects of lesions within their substance.

Functions of the Corpora Quadrigenina.—Among the investigators who have devoted special attention to these bodies may be prominently mentioned Adamuck, Knoll, Budge, Hensen, Voelkers, Flourens, Schiir, Ferrier, McKendrick, Gudden, and many others of note. Some have observed the effects of their removal in animals; others have studied the results of stimulation of their superficial and deep parts; while a few have recorded the results of destruction of the optic apparatus and certain convolutions of the cerebral hemispheres, as possessing a peculiar bearing upon points in dispute regarding these bodies. From these different sources a mass of evidence has been accumulated which appears in some instances to lead to contradictory conclusions. It is only by comparing the views of the investigators mentioned, and bringing to bear upon the subject what is also taught us by anatomical research, that the web may be partially disentangled.

The connection of the anterior quadrigeninal bodies, or the *nates cerebri*, with the optic tract and the sense of sight appears to be far more intimate than that of the posterior lobules, or *testes cerebri*, as was first pointed out clearly by Gudden. This observer found that the extirpation of the eye on one side of a young animal was followed by a degeneration and atrophy of the *natis cerebri* and its brachium; the testis and its brachium remaining unaltered. This view is apparently sustained also by the fact that the mole has the *testes cerebri* largely developed, whereas the *nates cerebri* are markedly atrophied. Adamuck believed that he had clearly demonstrated the existence of a centre within the *nates* which

¹This article formed a part of my course of lectures during the winter of 1882-83 before the students of the Medical Department of the University of the City of New York.

presided over those movements of the eye and pupil which are essential to the *accommodation of vision for near objects*, as well as the *co-ordination of all ocular movements*. Knoll found, however, that reflex contractions of the pupil remained after removal of the corpora quadrigemina; and Hensen and Voelkers have been apparently successful in mapping out the topography of the centres which preside over ocular and pupillary movements with greater accuracy than their predecessors. They were able to produce at will, by carefully applied electric stimulation in the region of the floor of the aqueduct of Sylvius, independent movements of the eye and pupil. In the dog, upon which animal these experiments were made, a centre which governed the *accommodation of vision*¹ was found to be situated in the posterior part of the third ventricle near to the aqueduct, while a centre for pupillary contraction and one also for its dilatation were found in the front part of the floor of the aqueduct of Sylvius, the former lying in the median plane and the latter more to the sides. The same observers state that a centre, which governs those muscles of the eyeball which are supplied by the third cranial nerve, can be found in the floor of the aqueduct, immediately behind that which presides over pupillary contraction. Whether we accept these statements as demonstrated or not, we know positively that such centres exist somewhere, and are so associated in their action that, when the eyeballs are directed inward and downward, as for near vision, the pupils are at the same time contracted; and when the eyeballs are directed upward and returned to a state of parallelism, the pupils are dilated to a corresponding extent. On the contrary, when the eyeballs are moved sideways in unison, the pupils remain unchanged. A most positive proof that the pupillary movements are not of a psychological nature is afforded by the experiments of Adamuck, who produced movements of *both eyes* by stimulation of the corpora quadrigemina of either side, and who also observed that the pupils were at the same time made to perform their proper movements. When, however, the corpora quadrigemina of the two sides were separated by a median incision, stimulation of the centres of either side caused movements of the corresponding eyeball only. In both experiments, changing the seat of stimulation caused modifications of ocular movements.

It was only after Knoll had shown that the reflex movements of the pupils remained after complete excision of the corpora quadrigemina, and the discovery of Hensen and Voelkers that the effects of stimulation of these bodies, as first practised by Adamuck, were not uniform until the *underlying parts* were directly reached, that discrepancies between these observers were explained.

To determine the true relations which these bodies bear to the special sense of sight is perhaps one of the most difficult problems in physiology.

Flourens and many subsequent observers have shown us that unilateral extirpation of the corpora quadrigemina in mammals and birds leads to a blindness of the opposite eye; and even when the cerebral hemispheres are removed without disturbing these bodies, that an apparently crude vision still remains. We have many experiments, however, to show that destruction of certain convolutions of the cerebrum also produced the most profound effects upon vision in spite of the undisturbed action of the quadrigeminal bodies. When we discussed the optic thalamus,² it was also stated that many clinical observations pointed toward the existence of a centre within that body which in some way modified or presided over visual impressions. We know also that lesions within the so-called "internal capsule" of the cerebrum frequently produce most serious impairment of vision, and conjugate deviation of the eyes.

Now, how are we to explain, theoretically, such contradictory phenomena? What views are we apparently justified in holding (from the standpoint of our present knowledge upon the subject) regarding the relations of the cerebral cortex, corpora quadrigemina, corpora geniculata, optic thalami, and internal capsule of the cerebrum, to the fibres of the optic tracts and the external organs of sight?

I think we are justified in attributing to the cells of the *cerebral cortex* or the external gray matter of the hemispheres alone our conceptions of the external world, as portrayed to us by means of the sensory nerves and the special senses. No matter how many collections of gray matter may be interposed along the course of the nerve-fibres which convey these impressions to the cortex (each of which may possibly help to modify them), there is no argument which has yet been advanced which tends to overthrow this general law. Every image cast upon the retina, every sound-wave which enters the external ear, every odoriferous particle which reaches the nose or is placed upon the tongue, every manner of form by which we are brought into direct or indirect relation with surrounding objects during life, becomes a *conscious impression* only by affecting in some unknown way the cells of the cerebral cortex. Here, the image thrown upon the retina becomes to our mind the picture actually seen; the sound-wave becomes the musical note; the contact of the odoriferous particle is transformed by the brain-cells found in its external gray matter into a sense of smell or of taste; objects become recognized as smooth or rough, hard or soft, heavy or light, only when these silent workers become thrown into activity by some sensory impulse carried to the convolutions of the brain by means of nerve-fibres.

We have reason to believe that the fibres of the optic nerve reach the gray matter of the convolutions of the cerebrum by different routes, and that each bundle meets (somewhere in its course) an interrupting mass of gray matter, with the cells of which the nerve-fibres become associated, and from which cells they are subsequently prolonged to those of the cortex. This is the common method of arrangement of all nerve-fibres, after they enter the substance of the brain or spinal cord, to which the optic fibres are no exception. The interrupting cells of the optic fibres are comprised chiefly within the optic thalami, the corpora geniculata, and the corpora quadrigemina. Stilling believes that a bundle of fibres can be traced to the *corpus subthalamicum*, and another to the *medulla oblongata*. The so-called "*basal optic ganglion* of Meynert" is thought by some to be also connected with a slender fasciculus of the nerve.

When speaking of these interpolated masses of gray matter and their controlling action upon all impulses sent to the brain, Michael Foster makes use of the following words, which I quote on account of their applicability to the subject under consideration:

"All day long and every day, multitudinous afferent impulses from eye, and ear, and skin, and muscle, and other tissues and organs, are streaming into our nervous system; and did each afferent impulse issue as its correlative efferent motor impulse, our life would be a prolonged convulsion. As it is, by the checks and counter-checks of cerebral and spinal activities, all these impulses are drilled and marshalled and kept in orderly array till a movement is called for; and thus we are able to execute at will the most complex bodily manœuvres, knowing only *why*, and unconscious or but dimly conscious *how*, we carry them out."

The study of the course of the individual fibres of the optic nerve in the region of the optic chiasm (Fig. 1) is rendered particularly difficult by the curved direction which they take; hence the relative proportion of the longitudinal and decussating bundles is still a subject of dispute among authorities upon that subject. Stilling states that inter-retinal fibres, which have no cerebral connection, can be demonstrated, while other authors

¹ This centre manifested an apparent control over the *ciliary muscle* only, and created alterations in the antero-posterior measurement of the crystalline lens of the eye.

² This lecture was published in the *Journal of Nervous and Mental Diseases*, April, 1883.

deny it. Some assert that all of the fibres, which are prolonged into the optic tract, decussate in man, as they are known to do in the lower vertebrates and some mammals, but pathological observation tends to confute this view. Charcot advances the somewhat attractive theory that those fibres of the optic nerve which do not decussate at the chiasm are continued along the optic tract of the corresponding side and eventually decussate, probably within the substance of the corpora quadrigemina, after which they are continued into the internal capsule of the opposite hemisphere. He sustains this theory on pathological grounds; since many recorded cases, where lesions of the internal capsule have been associated with symptoms referable to the optic nerve, have apparently demonstrated that *hemianopsia*¹ never (?) occurs. This could not be the case without a second decussation, provided the view be considered tenable that a complete decussation does not occur at the chiasm. The following diagram will make this apparent :

FIG. 1.—A diagram designed to show the course of fibres within the optic nerves, and some of the more important relations of the same. A, A', A'', and D, D', D'', fibres which do not cross at the chiasm, but probably do at the corpora quadrigemina. C, C', and B, B', fibres which do decussate at the chiasm. The relations of these fibres to the "internal capsule" of the cerebrum is also shown. This portion of the cerebral hemisphere is shown to be in relation with the fibres distributed only to the opposite eye; hence, lesions within it tend to produce "crossed amblyopia." The relation of bundles within the chiasm is made apparent. The fibres of the chiasm which connect the two eyes directly (inter-retinal fibres), and those which connect the two cerebral hemispheres directly (inter-cerebral fibres), are not shown, because they have no bearing upon symptoms, even if their existence is to be considered as demonstrated.

It is known that destruction of the retina in the dog gives rise to a degeneration of nerve-strands in both optic tracts. The chiasm of the cat has been divided without destroying vision, thus warranting the inference that the decussation at that point is incomplete. All the experiments which have been made to determine the relation of the cortex cerebri to vision are in favor of an incomplete decussation, because the sight of both eyes has been impaired by unilateral lesions. A large number of cases have been reported where lesions affecting one optic tract have produced hemianopsia of both retinae. Possibly the corpora quadrigemina preside over other functions in addition to the special sense of sight. Flourens was the first to notice that injuries of the corpora quadrigemina of one side produced peculiar phenomena, called "*forced movements*," and that the complete removal of these bodies caused inco-ordination of movement. These experiments have been repeatedly verified. In the frog, the removal of the optic lobes causes an almost entire loss of the power of co-ordina-

tion of movements required to preserve its balance; but it can still perform a variety of movements where co-ordination is demanded, such as swimming, leaping, etc. Schiff has attributed these effects, however, to injury of deeper parts (*crura cerebri*). We have already considered phenomena which are somewhat similar when the cerebellum was under discussion; and we have as yet no positive knowledge of the physiological connections between the optic lobes and the cerebellum.

The sense of sight has a marked effect upon co-ordination of movement, as we all know. Dizziness often follows the close inspection of a water-fall, or the rapid flight of objects before the eyes. The effect of extreme elevation from surrounding objects frequently produces marked disturbances of equilibrium. These facts seem to sustain the belief that the optic fibres must be closely associated with the cerebellum, pons Varolii, or *crura*, and the discovery of Flourens is an additional argument in its favor.

Finally, it is believed by some that a centre which presides over the secretion of sweat is situated somewhere in the region of the optic lobes.

EFFECTS OF LESIONS OF THE OPTIC CENTRES AND OPTIC NERVES.

In connection with the discussion of the corpora quadrigemina and the probable course and distribution of the nerves of sight, it seems to me an appropriate time to mention some interesting phenomena pertaining to vision which have an important bearing upon the localization of intracranial lesions. Before doing so, however, it will be necessary to hastily review a few important facts which are essential to a complete understanding of the subject. The optic apparatus may be said to comprise the following parts :

1. *Certain cortical centres*, which act as the *interpreters* of visual sensations transmitted to the convolutions by means of the nerve-fibres within the white substance of the cerebral hemispheres. These centres probably transform all impulses (which start originally as retinal impressions) into *conscious visual perceptions*.
2. *Nodal masses of gray matter*, with which the optic nerve-fibres are intimately associated before entering the white substance of the cerebral hemisphere. These masses include the corpora quadrigemina, the corpora geniculata, the corpus sub-thalamicum, the optic centre of the thalamus (Luis), the basal optic ganglion (Meynert); and probably some centres situated within the medulla oblongata. It is not possible to speak with positiveness concerning the seat of all the interpolated masses of nerve-cells associated with the optic nerve-fibres. Possibly some important ones may have been omitted, whose existence and function will be clearly demonstrated by future research. These interrupting ganglia probably exercise a *modifying influence* of some kind upon the impulses which are conducted to them from the retina; and subsequently allow them to pass to the cells of the cerebral convolutions so altered or *materialized* as to be readily transformed into conscious perceptions of external objects recognized by the eyes. It is not known what the special function of each of these interrupting masses is, nor can it be determined except through a more complete knowledge of cerebral architecture and pathology than we now possess.
3. *Nerve-fibres within the optic nerves and the optic tracts*, the latter being the prolongation of the former behind the chiasm (see Fig. 1). These fibres convey all impressions made by objects external to the body upon the retinae by means of the organ of sight, to the interrupting masses of gray matter mentioned above. The waves of light, which enter the pupil and fall upon the retina, create in the structural elements of that membrane (probably in the so-called "*rods*" and "*cones of Jacob*") impulses which are conveyed by means of the optic fibres to the interrupting ganglion-cells, and then to the convolutions of the cerebral hemisphere where these impulses

¹ A term used synonymously with *hemiplegia*; but a preferable one, since it signifies a blindness of one-half (lateral) of the retina.

become sight-impressions. It is evident, therefore, that anything which tends to interfere with the perfect conducting power of these fibres will impair the power of accurate conception of external objects revealed to us by means of vision, because the cortical centres are cut off from their retinal connections; hence the study of the course of the nerve-fibres and the relations of the nerve-tracts to surrounding parts becomes of vital importance to the advanced neurologist (the diagnosis of many cerebral and intracranial lesions resting entirely or in part upon optic phenomena which are to be interpreted from an anatomical standpoint alone).

4. *The retina, and its various structural elements.* This membrane constitutes the peripheral portion of the nervous optic apparatus. It is the only place in the body where the nervous system is so exposed as to admit of a direct examination, since we can see it by aid of the ophthalmoscope, and thus study its diseased conditions as well as its appearance in health. Physiologically, it is to be considered as the sensitive plate from which the details of outline and color of external objects, are telegraphed to the convolutions of the cerebrum. Many of the wonders of its construction were given you during the previous winter's course. Time will not now permit me to repeat them.¹

The experiments of Flourens, already quoted, first demonstrated that a *crude sense of vision* remains in animals which have been deprived of their cerebral convolutions above the level of the corpora quadrigemina, and many subsequent observers have attested to the accuracy of his conclusions. These experiments point to some functions within the masses of gray matter that are associated with the optic fibres, which bear a close analogy to those of the cortical cells of the so-called "visual area" of the hemispheres. We are forced to accept the view that these ganglionic masses take cognizance of visual impulses in an imperfect way, although the cerebral convolutions seem to be essential to a complete transformation of visual impulses into sight-perceptions. Section of the optic fibres after they leave the brain invariably destroys sight, thus proving that the retina itself has no inherent power of interpreting visual impressions which are cast upon it.

FIG. 2.—A diagram designed to show some of the relations of the optic nerve-fibres to surrounding parts. F, frontal lobes of cerebrum; P, parietal lobe; T, temporo-sphenoidal lobe; S, fissure of Sylvius; R, fissure of Rolando; O, occipital lobe; C, cerebellum; M, medulla oblongata; 1, corpora quadrigemina; 2, optic tracts; 3, optic chiasm; 4, optic nerves; 5, olfactory nerve; 6, motor oculi nerve; 7, trigeminus nerve; a, basis cranii; b, tegmentum cranii. The circles in the parietal lobe represent the cortical visual centres of Ferrier; the diamonds in the occipital lobe, the cortical visual centres of Munk. The cerebellum and pons Varolii are shown as if separated from the cerebrum, in order to make the relations of the crus to the optic tracts apparent.

Now, from what has been stated, we can classify lesions which may affect or destroy the visual function as follows:

1. *Lesions of the retina, or of some of the other struc-*

tures of the eye which prevent the formation of images within it.

2. *Lesions of the optic nerve*, anteriorly to the chiasm, at which point the decussating fibres have crossed each other.

3. *Lesions of the optic tracts and the chiasm*, or of parts so adjacent to them as to create pressure upon the optic fibres.

4. *Lesions of those ganglionic masses* whose connection with the optic fibres has been demonstrated by anatomical or pathological research.

5. *Lesions of certain regions of the cortex cerebri*, which have been shown to be in intimate association with vision.

6. *Lesions of the internal capsule of the cerebrum*; or of such parts of the medullary centre of each hemisphere as contain fibres connected with the "visual area" of the cortex.

The first set of causes of impairment of vision belongs properly to the province of the oculist rather than of the neurologist, although there is one condition which should always be sought for when cerebral disease is suspected, viz., *neuro-iritis*, or the so-called "*choked disc*." The evidences of this condition are afforded by the ophthalmoscope alone, because vision is not impaired in the early stages. Its existence is recognized early by tortuosity of the veins of the fundus of the eye, swelling of the optic nerve, and obscuration of the margin of the disc; later, the outline of the disc becomes unnaturally sharp and distinct, the nerve atrophies, the vessels become very small, the fundus is unnaturally pale, and vision is impaired. This condition is always (?) bilateral, although it is not uncommon to note a marked difference in the severity of the changes in the two eyes. Special attention is called to this disease of the eye, because it is now considered as one of the most reliable signs of conditions of the cerebrum which tend to produce a *gradually increasing pressure*, particularly of tumors; and in the second place, because its existence is liable to be overlooked, since vision is not impaired early. The various phenomena which are due to paresis of ocular muscles,¹ and which have often the most positive value in definitely localizing cerebral disease, cannot be considered under this set of symptoms or in this connection, because they do not govern in any way the sense of sight, although they assist the eye to focus images of objects upon the retina. My friend, Dr. W. C. Ayers, has lately made a valuable contribution to medical literature in the form of a brochure upon the value of the ophthalmoscope as an aid in general diagnosis,² which may well be consulted by all who desire the latest information in regard to the utility of this instrument, and the intimate relationship which exists between the eye and the body, as revealed by clinical study.

The second set of causes of impairment of vision (lesions of the optic nerve anteriorly to the chiasm) includes chiefly those conditions within the orbit which create pressure upon, or destruction of, the optic nerve after it leaves the cavity of the cranium. It is evident from the diagram (Fig. 1) that the impairment of sight in this case will be confined exclusively to one eye. The phenomena produced by disease within the cavity of the orbit upon sight must, of course, depend upon the amount of injury done to the optic nerve. *Blindness of one eye* indicates, as a rule, some exciting cause outside of the cavity of the cranium; if it occurs in connection with hemiplegia, or hemianæsthesia, however, a lesion of the internal capsule may be suspected, as shown in Fig. 1. Remember that either amblyopia or total blindness of one eye never occurs in connection with pressure upon the optic nerve-fibres either at the chiasm or behind it, and that some form of paralysis must coexist with these symptoms if the internal capsule be diseased.

We come now to the third set of causes, viz., lesions

¹ See pages 103 to 146 of the author's work, *The Applied Anatomy of the Nervous System*. New York: D. Appleton & Co. 1881.

² These will be found by consulting the author's work, *The Applied Anatomy of the Nervous System*. New York, 1881.

³ American Journal of the Medical Sciences, October, 1882.

(c.) The *bi-temporal variety* indicates atheromatous degeneration of the circle of Willis. Possibly (?) symmetrical lesions of the outer part of the chiasm might also cause it. I am not aware that the view of Charcot,

that a decussation of the optic fibres takes place within the substance of the corpora quadrigemina, is as yet sustained by a recorded case of bi-temporal hemianopsia produced by a circumscribed lesion within the optic lobes.

(d.) Finally, lesions of the *internal capsule* are often associated with *amblyopia*, or indistinct vision confined to one eye.

The bi-nasal, and also the bi-temporal varieties, are due (as a rule, at least) to lesions confined to the *anterior fossa* of the cranium; hence we sometimes find the *olfactory nerve* of the side corresponding to the seat of the lesion simultaneously affected, and creating anosmia (loss of smell) with or without subjective odors.

If the lesion be situated within the *middle fossa* of the cranium, the *optic tracts* will be affected, thus causing crossed hemianopsia; while the *motor nerves of the eye* may be simultaneously pressed upon, as they pass through that fossa on the way to their foramen of exit from the cranium (the sphenoidal fissure), thus producing more or less impairment of the movements of the eyeball of the same side. The value of these complications cannot be over-estimated, when they exist, because they are of the greatest aid in diagnosis, and often enable the skilled anatomist to positively determine the seat of the lesion.

FIG. 4.—A diagram of the base of the brain, designed to show the parts adjacent to the optic nerve tracts and chiasm. The nerves are represented by their respective numbers: II., optic; III., motor oculi; IV., trochlearis; V., trigeminus; VI., abducens; C, crus cerebri of each hemisphere; b, infundibulum, the pituitary body being cut off to show the optic chiasm; a, the corpus albicans (mamillary tubercle); e, external geniculate body; i, internal geniculate body. The dotted line which crosses the pons Varoli, connecting the roots of the fifth nerves, is Gubler's line, an important guide, since lesions of the *pons* in front of it causes "crossed facial paralysis." Lesions in the region of the *crus* may involve the third and second nerves simultaneously. Lesions about the chiasm may press upon the corpus striatum within the mass of the cerebrum. The *crus* comprises both the motor and sensory tracts of the cerebrum (see Fig. 5).

The *fourth set* of causes of impairment of vision (according to the classification which we have previously adopted) comprises all diseased conditions which are limited exclusively to those ganglionic masses through which the optic fibres pass in order to reach their connections with the convolutions of the cerebrum. If we confine ourselves to this strict limitation, we are forced to admit that little can positively be said respecting them which will bear upon intracranial diagnosis, because, to my knowledge, there are no recorded cases where evidences of cerebral disease have been confined exclusively to these regions. There are some symptoms, however, that may coexist with disturbances of vision when lesions exist in the region of the middle fossa of the skull; these may prove of assistance in deciding as to the seat of the lesion. Among them may be enumerated: 1. *Crossed paralysis* of the "third nerve and body" type, a condi-

tion characterized by hemiplegia and paralysis of the motor-oculi nerve of the opposite side. 2. *Crossed paralysis* of the "olfactory nerve and body" type, a condition characterized by hemiplegia and loss of smell in the opposite nostril. 3. *Hemiplegia*, or loss of the power of voluntary motion in one lateral half of the body. 4. *Hemianesthesia*, or a loss of sensation in one lateral half of the body. 5. *Ataxic symptoms*, indicating an impairment of co-ordination of muscular movements.

The first of these points positively to a *lesion of the crus cerebri*, if unattended by other symptoms. But, if evidences of disturbance of the optic tract (crossed hemianopsia) exists simultaneously with this form of crossed paralysis, it indicates that the lesion is large enough to interfere also with the optic nerve as well as the motor-oculi fibres within the *crus* and the motor tract of the *crus*. The symptoms of this variety of crossed paralysis¹ are so well defined as to render it almost impossible to mistake them.

The second condition may occur when the lesion is sufficiently large to create pressure upon the nucleus caudatus or other motor parts of the brain, thus causing hemiplegia of the opposite side; and, at the same time, to injure the olfactory nerve, thus causing anosmia (loss of smell) in the nostril of the corresponding side. Of course the optic tract or chiasm must be involved simultaneously when hemianopsia also exists. The tests for anosmia² have already been given in previous lectures.

FIG. 5.—A diagram designed to show the general course of fibres in the "sensory" and "motor tracts," and their relation to certain fasciculi of the optic nerve tracts (modified from Seguin). S, sensory tract in posterior region of mesencephalon, extending to O and T, occipital and temporal lobes of hemispheres; M, motor tract in basis cruris, extending to P and F, parietal and (part of) frontal lobes of hemispheres; C.Q., corpus quadrigemini; O.T., optic thalamus; N.L., nucleus lenticularis; N.C., nucleus caudatus; 1, the fibres forming the "tegmentum cruris" (Meynert); 2, the fibres forming the "basis cruris" (Meynert); a, fibres of the optic nerve which become associated with the "optic centre" in the optic thalamus, and are subsequently prolonged to the "visual area" of the convolutions of the cerebrum; b, optic fibres which join the cells of the "corpora quadrigemina," and are then prolonged to the visual area of the cerebral cortex.

Hemiplegia may occur in connection with hemianopsia when the lesion is of sufficient size to affect any part of the so-called "motor tract" simultaneously with the optic nerve-fibres. The motor paralysis is on the side opposite to the lesion, because the fibres of the motor tract decussate at the lower part of the medulla. Flechsig has shown that, in rare cases, *exceptions* to this general rule are to be explained by an abnormality in the decussation of the motor fibres. Hemiplegia is seldom observed in connection with hemianopsia alone, since the olfactory, motor-oculi, trigeminus, and facial nerve-roots are especially liable to be simultaneously involved (see Fig. 2). This explains the mechanism of the four varieties of "crossed paralysis" which are encountered, the hemiplegia being on the side opposite to the lesion, and the symptoms produced by paralysis of the cranial nerve being confined to the side corresponding to the lesion.

¹ See author's work on The Applied Anatomy of the Nervous System.
² Op. cit.

Hemianæsthesia indicates some disturbance of the nerve-fibres of the so-called "*sensory tract*," the loss of sensation being confined to the lateral half of the body opposite to the lesion which causes it, because the sensory fibres decussate in the spinal cord. In cerebral hemianæsthesia there is more or less insensibility to touch, pain, and temperature, and also abolition of muscular sensibility with complete retention of electro motor contractility. The mucous membranes of the eye, nose, and mouth are also anæsthetic. Now the upper portion of the sensory tract lies in the posterior regions of the crus cerebri and the internal capsule and crus, and is in close relation with the posterior basal ganglia. The fibres of the optic tract may be likewise affected simultaneously with lesions of the following parts: the crus, the internal capsule, the optic thalamus, the corpora quadrigemina, the geniculate bodies, and the medulla. It has been already stated that lesions of the internal capsule are often associated with *amblyopia*, but not with hemianopsia. Fig. 1 will make the probable explanation of this fact intelligible. Our ability to definitely locate lesions of the sensory tract, or of the ganglia connected with it, is, as yet, imperfect. It is only by the careful study of associated symptoms that conclusions can be arrived at.

Ataxic manifestations, occurring in connection with evidences of impairment of the sense of sight, open a wide field for speculation. The proximity and intimate structural relations of the cerebellum with the optic lobes, basal ganglia, crus, and medulla, suggest the possibility of cerebellar lesions when these two symptoms are present to a marked degree. The subject is too complex for discussion here. It will be more intelligible after the cerebellum has been considered.

The *fifth set* of causes of impairment of vision previously tabulated, will now be considered. Within the past few years the attention of physiologists has been directed, by some remarkable results of experimentation upon the convolutions of the cerebral cortex, toward the view that certain convolutions of the cerebrum were essential to perfect visual perceptions. To Flourens and some of the older observers, who had remarked that the removal of portions of the hemispheres, or serious injury to them, created blindness, the loss of sight appeared to be temporary. The fact (?) was explained in various ways, until Goltz called attention to the error of supposing that no permanent imperfections of vision remained after extensive injuries to the cerebral hemispheres. This author showed that the permanent results of such injuries might escape notice unless special care was used in the examinations of the animal. The peculiarities of the permanent impairment of vision are manifested only when the animal is subjected to tests which had been invariably potent before the cerebral injury. Thus the dog, from which portions of the cerebral hemispheres had been removed, fails to recognize his food by sight; when he is threatened by a whip he is not cowed; he is no longer affected by objects which caused him to be violently excited before the mutilation; he makes no response to the extension of the hand of his master for the paw; and yet this animal can see to avoid objects and to perform all varieties of movement, as well as in his natural condition. Another striking characteristic of this impairment of sight is, that under educational exercise recovery takes place. The dog may again be taught to fear castigation and to shrink at the sight of the whip; to recognize his food; to obey the motions of his master's hand, etc.

Two interpretations of these phenomena have been suggested. The first is, that the animal has imperfect visual perceptions, so that objects appear misty or as if seen through a gauze. Goltz suggests that they may appear as if all the colors were washed out, thus depriving food, dress, etc., of their characteristic appearances. The second interpretation supposes that the memory of past visual impressions is effaced, so that the animal for-

gets the pain of the lash, the taste of the food, the features of his master, the tricks which have been laboriously taught him. The first view is that of Goltz, who considers that the animal has to learn to use his imperfect visual perceptions before his intellectual faculties (which are presumed to be unimpaired) can respond to them in a proper way. The second view is that of Munk, who speaks of this form of imperfect vision as "psychical blindness," in contrast to "absolute blindness," which is the result of destruction of the optic fibres. The condition of the animal resembles that of the new-born. Retinal impressions have no associations connected with them. During the period of recovery the animal has to acquire a new memory, as it were.

With this distinction clearly in mind, we are prepared to discuss the views of Ferrier, Goltz, Munk, Luciani, Tamburini, Yeo, Dalton, and others respecting the exact seat of the visual centres within the cortex cerebri.

Goltz, in his experiments upon dogs, was unable to recognize any distinct areas which presided exclusively over visual impressions. He insists that disturbances of general sensibility accompanied the impairment of vision produced by destruction of the convolutions, and that the results depended upon the amount of brain-substance removed or destroyed. He found, however, that the locality operated upon influenced the phenomena which followed, and that recovery would take place if the injury was not too extensive. Goltz destroyed the brain by making a hole, or a number of them, through the skull, and using a *forcible stream of water* to wash away the brain-substance. The faults of the method may account for the negative results obtained by it.

Ferrier investigated the subject chiefly upon the monkey tribe (the nearest approach to the human race) and arrived at conclusions of a more positive character. This observer was led to adopt a more certain way of limiting the injury done to the cortex than that of Goltz. His conclusions may be thus summarized: When the "angular gyrus," or a convolution of the parietal lobe, so called from its shape, since it forms a sharp angle (see Fig. 2), was destroyed upon one side only, the vision of the *opposite eye* was destroyed for a time, but it eventually regained its powers. If the angular gyrus of each hemisphere was simultaneously destroyed, the *loss of sight was permanent* and both eyes were equally affected. Hence it would appear that each hemisphere is in some way connected with both eyes, because unilateral destruction of this convolution does not create permanent blindness, as it would do if the opposite hemisphere did not come to its relief. Dalton has lately confirmed the views of Ferrier by experiments made upon dogs, thus tending to confute the view of Goltz that the effects of cortical lesions depend more on their extent than on their position. The animals operated upon by this observer remained permanently blind, although the lesion was unilateral.

Munk has confined his experiments chiefly to the occipital lobes of the cerebrum, and has endeavored to demonstrate the existence of a "visual area," differing in position and of much wider extent than that of Ferrier (Fig. 2). He maintains that certain parts of this region can be shown to preside over *limited portions* of the retina, and that blindness of circumscribed spots in the retina can be artificially produced. He states that the "absolute blindness" thus created is commonly associated with "psychical blindness," from which the animal may recover by proper exercise and training, provided the whole visual area is not destroyed. This author attributes the recovery to a deposition of new visual experiences in the rest of the visual area.

Some observations which have lately been made in support of the view that the occipital lobes of the cerebrum are more directly associated with the mental faculties than the frontal lobes are of special interest to those who agree with Munk regarding the seat of the visual area of the cortex. At present, however, the subject must be regarded as unsettled.

The *fifth set* of causes of impairment of vision, previously tabulated, has been discussed in part in connection with the others. We have a mass of clinical as well as experimental evidence to show that destructive lesions situated within the *posterior one-third* of the internal capsule cause *hemianæsthesia* on the opposite side of the body. As regards vision, the symptoms which sometimes exist are especially noteworthy. There appears to be developed on the anæsthetic side a partial blindness of the eye (*amblyopia*), and the *field of vision for color* is remarkably contracted, as first pointed out by Landolt. In the normal eye the field for blue is the largest; next comes that for yellow; then orange, red, green, and violet have fields of gradually diminishing size, the last being perceived only by the most central parts of the retina. Now, in connection with hemianæsthesia caused by cerebral lesions, the perception of violet first disappears, then for green, and later for orange. In some cases yellow and blue can be perfectly recognized; but in the higher degrees of anæsthesia all colors merge into an uniform sepia tint. Another important fact has been pointed out by Landolt, viz., that the eye on the same side as the lesion participates, though to a less extent, in the loss of color-perception.

Now, if the eyes be examined with the ophthalmoscope, no evidences of organic lesion of the retina or degeneration of the optic nerve can be detected until the disuse of the organ has induced atrophic changes. It is noteworthy that hemianopsia does not occur, a fact which Fig. 3 will help to explain. From statements which have been made in preceding pages, we are forced to conclude that this peculiar type of blindness is never caused except by lesions which are situated or act below the cortex. It is more commonly met with in connection with hemiplegia than hemianopsia. The effects of lesions of the internal capsule upon other nerves of special sense will be considered later.

Clinical deductions drawn from preceding pages.—*Amblyopia* of one eye can result from lesions involving the optic nerve in front of the chiasm, or from lesions of the internal capsule. If from the latter, the field for color-perceptions will be found to be markedly contracted or color-vision will be wanting; both eyes may be affected, the most marked changes being found, however, in the eye opposite to the seat of the lesion. We have not sufficient data for positive clinical deductions respecting lesions of the visual area of the cortex in man. The blindness of the opposite eye appears to be absolute, while it lasts, in all animals upon whom the experiment has been tried.

Hemianopsia only occurs when the *optic tracts* or the *optic chiasm* are pressed upon or destroyed by lesions in the region of the base of the cerebrum. It is evident, therefore, that the trephine cannot afford relief of this symptom. When syphilitic gummata may be suspected, the prognosis is extremely favorable if active treatment be employed. The variety of hemianopsia indicates the seat of the lesion with great exactness.

If *paralysis* (in any of its forms) coexist with hemianopsia, a valuable guide will often be afforded in determining the extent of the lesion.

Crossed paralysis of the "olfactory nerve and body type" indicates a localized pressure which is chiefly exerted upon parts *within the anterior fossa of the skull*. The motor tract is probably involved by upward pressure upon the caudate or lenticular nucleus, or the fibres of the internal capsule; thus accounting for the hemiplegia of the opposite half of the body. The olfactory nerve, which lies near to the optic chiasm, is affected by pressure in the downward direction, and the optic chiasm or tract may be simultaneously involved; hence, a loss of smell in the nostril on the same side as the lesion may coexist with some form of hemianopsia, as well as with a crossed hemiplegia.

Crossed paralysis of the "motor-oculi nerve and body" type indicates a lesion situated *within the crus cerebri*.

If hemianopsia be present in connection with this condition, it proves conclusively that the optic tract, which lies in close relation with the crus, is simultaneously affected by the lesion. We find, therefore, that the eye on the same side as the lesion is blind in its temporal half if the optic tract be involved; that it can no longer be turned toward the nose or made to act in parallelism with the opposite eye; that the pupil is dilated; and that the upper eyelid droops over the eyeball, giving it a sleepy appearance. On the side opposite to the lesion the eye is blind in its nasal half, and the body is hemiplegic. There are few conditions which are of greater clinical importance than this type of crossed paralysis, because the seat of the lesion is positively indicated. ‡

Choked disc is a common symptom of lesions of the base of the cerebrum, and of any intracranial disease which produces a gradually increasing pressure. It is specially diagnostic of tumors. It is not associated with impairment of vision until late, so that it is often unsuspected when present. The ophthalmoscope is necessary for its detection. It may coexist with hemianopsia, and is always bilateral. It is a positive contra-indication to trephining.

Lesions at the base of the skull may *cross the mesial line*, and still involve only one optic tract. If this occurs, the hemianopsia will be accompanied by other symptoms of diagnostic importance, no longer confined to one side. Double anosmia, general paresis or complete paralysis, general anæsthesia, and paralytic symptoms referable to both eyeballs might be thus produced. Lesions of this character are more liable to affect the chiasm of the optic nerves than the optic tracts; in either case, however, hemianopsia would result, and its type would be a reliable guide to the seat of pressure (see Fig. 4).

Crossed paralysis of the "facial nerve and body type" is not as liable to coexist with hemianopsia as the two forms previously mentioned. The reason for this is a purely anatomical one. The symptoms of facial paralysis are too involved to be given here in detail.¹

Uncomplicated hemianopsia indicates that the effect of the lesion are confined to the optic tracts of chiasm, and that no pressure-effects are exerted upon the motor or sensory projection tracts, or adjacent nerves.

Aphasia sometimes coexists with hemianopsia. I have met with two instances of this kind. In one there was slight paresis of the left side, tending to prove that aphasia can occur with lesions involving the right hemisphere. Both were cured with specific treatment. We must attribute the development of this complication to pressure upon parts in the neighborhood of Broca's centre.

Lesions confined to the crus cerebri seldom create impairment of any of the special senses excepting that of the sight. These cases are not associated with impairment of intellect or of speech. It has been claimed that severe lesions cause paralysis of the bladder, but I have never encountered it. Many points of interest pertaining to lesions of the crura will be considered later in the course.

FEEDING SYPHILITIC INFANTS.—At l'Hôpital des Enfants Assistés in Paris, where many of the waifs and foundlings of the city are cared for, a unique feature has been introduced by M. Parrot, consisting of a nursing service for syphilitic infants. The nurslings draw their nourishment directly from the teats of the ass, to which they are presented five times during the day, and three times at night. They thrive under this treatment, and seventy per cent. live, while almost all formerly died when fed from the bottle (*Boston Medical Journal*). After all, why should they not thrive? Would they not have been nursing asses' milk if they had been imbibing from the maternal mamma?

¹ They are fully discussed in the author's work on The Applied Anatomy of the Nervous System.

THE CHANGE OF MEDICAL OPINION IN REGARD TO THE CAUSE AND RECENT EXTENSION OF MALARIA.

By CHARLES P. RUSSEL, M.D.,

SANITARY INSPECTOR OF THE NEW YORK HEALTH DEPARTMENT, FORMERLY REGISTRAR OF VITAL STATISTICS.

THE most remarkable change in professional opinion, based upon long-accepted doctrine with regard to the cause of any particular disease, is to be found in the modification of their views by medical men, within recent years, upon the production of malarial disorders. Tradition, for centuries, usurped in this direction, as in many more, the domains of fact and of proof, which, in some instances, have now been fully conceded, but in others still present only a dubious claim to our recognition. Such appears to have been the history of those conditions or influences which have been supposed for centuries to be the primal and essential factors in the development of malarial diseases.

Probably the earliest monograph extant upon this subject is the famous one by Lancisi, entitled "*De Noxiis Paludum Effluviis*," published in Rome in the beginning of the eighteenth century. Lancisi's investigations were extensive and searching, and his conclusions seemed so irresistible that they were adopted by scientific men at once, and have since maintained, until within a very brief period, an assured place as truths in professional literature. Those who subsequently published medical works which needed to include diseases of a miasmatic character, accepted without question or farther investigation the opinions inherited, so to speak, from the learned Roman author. Thus they passed from hand to hand as the years rolled on, and finally reached our period, bearing such emblems of authority as to challenge and disarm criticism. During the lapse of time some few additions were gradually made to the supposed knowledge upon this subject, all of which, however, had their foundation in the original assumption, namely: that malaria essentially depends upon circumstances existing in the *simultaneous operation of air, moisture, and a certain high range of temperature, causing vegetable decomposition*.

Of later years, while not denying the necessity of these conditions, a new and attractive theory led many observers to endeavor to go still farther back, and discover the remote or ultimate cause of these, as well as of all zymotic affections, in minute particles called germs, having special shapes and characters peculiar to each individual disease. Hence what is dignified with the title of the "Germ Theory." Now, what are germs? The ordinary mind cannot even conceive of their form or nature. But what is called the scientist (or, in this case more properly, experimentalist) has a large number of them in his "mind's eye," but none in his laboratory, they being, as far as we yet know, so immeasurably small as to elude observation under the most powerful microscope magnifying thousands of diameters.¹ They may be regarded as the minute and evanescent ghosts of defunct vegetable and animal molecules, and yet many of them have received polysyllabic names. They are presumed to represent something akin to atoms of diseased matter.

In this connection I may be permitted to quote the following remarks of W. Mattieu Williams, F.R.A.S., F.C.S., upon the address, in 1871, of Sir William Thomson before the British Association, treating of atoms: "After hearing all these oracular utterances concerning

atoms, the unsophisticated listener will be surprised to learn that no human being has ever seen an atom of any substance whatever; that there exists absolutely no direct evidence of the existence of any such atoms; that all these atoms, of which Sir William Thomson speaks so confidently and familiarly and dogmatically, are pure figments of the imagination. He will be still further surprised to learn that the bare belief in the existence of ultimate atoms as a merely hypothetical probability is rejected by many of the most eminent of scientific men, and that among those who have disputed the idea of the atomic constitution of matter is the great Faraday himself; that the question of the existence or non-existence of atoms has recently been rather keenly discussed; and that even on the question of the permissibility of admitting their *hypothetical* existence, scientific opinion is divided; and that such a confident assumption of their existence as forms the basis of this part of the President's address is limited to only a small section of mutually admiring transcendental mathematicians."

This arraignment of the atomic theory applies with equal force to the germ theory and to its supporters. Assuming vegetable decomposition to be an essential element in the production of malaria, a number of investigators have employed much time in endeavoring to discover specific germs, only a few of which, it has been assumed, introduced into the system, usually by inspiration, would almost certainly multiply a million-fold, and manifest their presence by well-known and characteristic symptoms.

Some twenty years since, Dr. Saulsbury, an American physician of the West, created quite a sensation in the profession by the announcement that he had discovered the veritable germ of malaria. He christened it "*pal-mella*." At first glance he seemed to have actually demonstrated a fact. But it is unnecessary to enumerate his experiments, as they have since been proven to be valueless and absurd. About the same time similar observations in certain malarious districts of Europe, especially in the historical miasmatic regions of Italy, were announced, but with equally negative results. Dr. Ballestra was quite confident that some spores and sporangia of a little algoid plant, which he found in the air overlying the Pontine Marshes were the long-sought for things.

Two French observers, Lemaire and Gratiolet, made a similar discovery after examinations of one of the most unhealthy marshes of Sologne, in the shape of "spherical, ovoid, and fusiform spores, and a large number of pale cells," which were afterward shown to be products of vegetable putrefaction, existing in most swamps, whether innocuous or not. Quite recently two other observers—Krebs of Prague, and Tommasi Crudeli of Rome—were certain that they had finally traced the infinitesimal being into its lair. They conferred upon it the name of *bacillus malarie*. They injected it into rabbits, dogs, etc., and maintained that the result in these animals was undoubted malarial fever. Their investigations were undertaken in the Agro Romano during 1879. They examined minutely the lower strata of the atmosphere in the district mentioned, together with its soil and stagnant waters. In the air and soil they found a microscopic fungus, consisting of numerous movable shining spores, of a longish, oval shape, and nine micromillimetres in diameter. This fungus they generated in various kinds of soil. The fluid matter thus obtained was filtered and repeatedly washed; and the residuum left after filtration was introduced under the skin of healthy dogs and rabbits. The microscopical particles remaining after washing considerable quantities of the surface soil were employed in similar manner. It was affirmed that all the animals experimented upon developed typical malarial fever, showing regular intervals and lasting various lengths of time up to sixty hours. There was likewise observed an increase of animal temperature, during the shivering fits, up to 42° C., the normal temperature being from 38° to 39° C. The animals so af-

¹ Pettenkofer is quite positive as to the manner in which disease-germs operate. According to him, a germ, in order to produce disease, must not only find a susceptible subject, but must also meet with that subject in a favorable locality and at a proper time; and as disease-germs are not generally very long-lived, the vast majority of them are extinguished without encountering such essential conditions. Otherwise the human race would speedily disappear. The Chief of the Micrographical Department of the Paris Observatory has recently announced a more wonderful discovery than any found hitherto with regard to germs. It seems that he has succeeded in enumerating them as follows: Their number in each cubic metre of the atmosphere of Paris amounts in winter to 7,000; in May, to 12,000; in June, to 35,000; in August, to 23,000; in October, to 14,000; and in November, to 8,000!—*St. James' Gazette*. The indefatigable Professor Hallier, of Jena, Germany, has observed in hydrophobic saliva a characteristic germ, upon which he has conferred the name of *Lyssophyton*.

fected were described as exhibiting acute hypertrophy of the spleen, similar to that noticed in human patients suffering from the same trouble—and in the spleens of the diseased animals a large number of the characteristic fungi were present. More lately Drs. Marchiafava and Valenti of Rome have affirmed that they detected the bacillus malarie in human subjects, in a more advanced stage than in the animals experimented upon by Krebs and Tommasi Crudeli.

According to a still more recent assertion of Tommasi Crudeli,¹ results of farther pathological investigations show that the bacilli may always be detected in the blood during the febrile invasion; but that during the crisis they disappear, leaving only spores. According to the researches of Laveran, extended and corrected by Richard, the blood in malarial fever contains, during the accession, spherical organisms developed in connection with the red globules, and furnished with filaments; also certain curved and pointed bodies, *which are only infected and deformed blood-corpuscles*. The pigment granules of malarial blood are produced in the red corpuscles during the growth of the organisms. I have cited these somewhat hyper-scientific and conflicting accounts of assumed discoveries, not to discuss them particularly, but to remark that their fallacies have been detected, and that such examinations, though interesting, bring us no nearer to a solution of the question, *What is the nature of the malarial cause?* All of the different substances and forms, however minute and unknown before, discovered thus far in malarious localities, may be and have been found as well in districts perfectly salubrious.

In the August (1876) number of the *Popular Science Monthly* I published a brief account of the views then entertained almost universally as to the conditions from which malaria was regarded as springing, views in which, at that time, I concurred. Since then, however, I have been forced to materially modify my opinions on this subject. During a conversation some few years since with the late Dr. Hayes, the Arctic explorer, I was surprised to learn that malarial disease was not unknown in certain Arctic regions where the summer temperature almost never rose above 60° F., with an average for the warmest month of only about 45°. Dr. Hayes him-

self had treated several cases of intermittent fever among the natives there. This disposed at once of the tradition that an average summer temperature of at least 59° F. is one of the essential factors in the causation of such disorders.

Investigating the subject more thoroughly, I found many instances of the occurrence of malarial diseases in other places where vegetable decomposition was, to any great extent, impossible; and very many more instances exist, as everybody knows, of spots where all the so-called conditions for the production of the malarial poison have always been present without such poison ever having manifested itself; and others still, in which, under similar circumstances, it has appeared only at rare intervals. The doubts thus excited were subsequently corroborated during a professional connection with several cases of mill-dams alleged to have produced malaria, one of which I will allude to hereafter. Within a few years the assumption of the truth of the convictions upon this subject entertained by most physicians and hygienists has been the basis for a war upon mill-dams in the Middle and Eastern States. Assuming that the exposure periodically, by drawing off water, of lands contiguous to a stream, and, in fact, forming a portion of the river-bed when the mill-dam was full—such drawing off of a certain quantity of water laying bare a considerable area of submerged ground covered with vegetable growth—and that the action of the summer sun upon such vegetation must inevitably create malaria—there could be little question as to the deleterious influence of any mill-dam within certain latitudes upon the health of the neighboring community. But, unfortunately for this theory, there are thousands of mill-ponds, within the specified regions of average summer temperature, presenting every prescribed condition for the creation of malaria, in whose vicinity chills and fever have always been unknown as much as yellow fever or the plague.

In this connection it is proper to recall the fact that since the United States Census of 1870 there has been particularly noticed an evident extension of the subtle miasmatic influence over regions previously exempt from it within the Middle and New England States. The additional effect of this disease-wave upon the naturally malarious site of New York City alone in this period was exhibited in the fact that from 1868 to 1872 the number of annual victims to these fevers increased three hundred and fifty per cent. It is well known that in places previously exempt from them miasmatic fevers occasionally appear and disappear without there having taken place any perceptible changes in the relations of the soil. Sometimes such fevers assume a widely epidemic or pandemic character, appearing to have broken loose from their native haunts in order to invade a great extent of territory. Thus, as Hertz and Proust inform us, the continent of Europe was almost entirely overspread by such pandemics in 1558, 1678, and 1679; from 1718 to 1722; from 1808 to 1811; from 1824 to 1827, and from 1845 to 1848. That the cause of malaria being thus disseminated is equally mysterious with that of most epidemics few will venture to deny.

When inquiring why malarial fevers should prevail for any considerable time in a given region, we must divest our minds of preconceived notions, and examine the matter judicially. We shall thus find that a variety of different circumstances seem to be connected with the prevalence of such diseases in different localities; and these last may be classified as follows:

1. *Essentially Malarious Districts.*—Here, as far as known, malaria has *always existed*, and analogously always will. Manhattan Island, together with its surroundings—Westchester County, Northern Long Island, and Eastern New Jersey—present the most familiar examples. While in some portions of these territories the existence of swamps and overflowed lands does appear to bear a positive relation to malarial affections, and their drainage does seem to be followed by a *diminution*

¹ The latest publication by this gentleman, who is a Deputy to the Italian Parliament, and, so to speak, the present apostle of the theory which ascribes the production of malaria to a ferment consisting of germs, termed by him *schizomycetes bacillaires*, is a report, dated March 18, 1883, to the Italian Minister of Agriculture, Industry, and Commerce, upon proposed legislation, having in view the general suppression of malaria throughout Italy, but more especially in the Roman Campagna. He appears to regard so herculean an undertaking as feasible under administrative pressure. His plan would involve an extensive concerted system of thorough cultivation (*cultures intensives*) and drainage, for the destruction and prevention of said ferment, which, as he avers, can be set free only under three indispensable conditions, viz.: "1, a temperature of about 20° C. (68° F.); 2, a moderate amount of soil humidity; 3, the direct action of the oxygen of the air upon those portions of the soil containing the malarial ferment; and should but one of these conditions be wanting, the development of malaria is suspended." Besides these extensive agricultural measures of relief, he insists also upon the universal administration of arsenic in prescribed doses and solid form to the farm-hands throughout the malarial regions of the country. He does not even suggest any means of enforcing a scheme calling for arbitrary radical changes in the various agricultural systems pursued by an immense number of farmers, fruit-growers, herders, etc. He questions the efficacy of quinine as a prophylactic, although few of our army surgeons who employed it for that purpose during the War of the Rebellion, will, I judge, be found to agree with him. In my capacity at that time as the Medical Inspector of the Fifth (Regular) Corps of the Army of the Potomac, I had occasion to observe the prophylactic effects of quinine, not only in my own person, but in that of very many others. I need scarcely add that most of the numerous and fatiguing campaigns of that army were conducted during the hot season, in regions fully as malarious as almost any of Italy. Tommasi Crudeli likewise differs from the generality of so-called authorities in restricting the rise of the malarial ferment to merely a few feet perpendicularly ("four or five metres").

He gives examples of large numbers among the equine and bovine species having suffered severely from malaria. Strangely enough, his experiments, and those of Marchiafava and Caboni, with the malarial ferment infecting the human system, have been conducted, so far as I am aware, almost exclusively upon dogs and rabbits, animals which are not proven to suffer from malarial invasion in the regions referred to. I have myself seen some fine English hunting-dogs imported into Rome, and constantly used for the chase in the malarious hunting grounds of the Campagna and Pontine Marshes without suffering any ill effects whatever. The hares and rabbits of Italy equally escape such attacks, if their appearance indicates anything. Moreover, those who perform exceedingly timid nature of that beast, it exhibits, when handled, a marked rise in animal temperature. Another singular fact, gravely set forth by Tommasi Crudeli, is the necessity of obtaining blood only from persons suffering with *pernicious fever*, in order to produce intermittent symptoms in the lower animals. Thus he confesses that, although he had made extensive preparations for such experiments during the year 1882, he refrained from trying them, because not a single case of *pernicious fever* was received during that period into the Roman hospitals. He hopes to be more fortunate, however, within the present year.

of such diseases (*never, however, by their entire suppression*), in other instances the drainage of such places has been succeeded by a positive increase, rather than a subsidence of miasmatic troubles. We are, therefore, placed in a dilemma as regards the influence of drainage in exterminating malaria. On the other hand, whether in miasmatic regions or elsewhere, I do not presume to deny that *thorough* drainage has a beneficial effect upon the *general* public health, when we consider the large category of diseases. But this result proves nothing as to the *cause* of malaria.

2. *Non-malarious Districts.*—Here malaria has appeared only occasionally, and at irregular intervals and with a limited period of existence; for, according to its previous history in such territories, its disappearance sooner or later was inevitable. Dr. Oliver Wendell Holmes' admirable description of similar events in various portions of New England during colonial days substantiates this fact. New York State, New Jersey, and Pennsylvania are largely exempt from *endemic* malaria, but have been afflicted from time to time in certain parts with invasions of *pandemic* malaria. We are entirely ignorant of any laws governing these erratic outbreaks.

3. *Elevated lands, even lofty mountains and extensive dry sandy plains, where none of the so-called conditions for malaria can be discovered in simultaneous operation, but where malaria is virtually constant.*—Such instances are very numerous, and stagger even the most ingenious of the swamp and germ theorists. To these gentlemen it may seem almost sacrilege that any intelligent reader and observer should become an iconoclast as to the idols which ages of study have built up for all future worship—nevertheless, so it is; and it is significant that some of the most distinguished scientific men have lately abjured the orthodox opinions in regard to the essential conditions for the production of malaria. In a *cause célèbre* tried at Pittsfield, Mass., in October, 1882, on account of an indictment brought against the owners of a mill-dam for creating malarial fevers, Dr. Paul A. Chadbourne, President of the Massachusetts Agricultural College, and ex-President of Williams College, testified that, as a professor in the Berkshire and Maine medical schools he had formerly lectured upon the nature of malaria. He then believed it to be of gaseous character, due to heat and decomposition of vegetable material, but he had since entirely abandoned that theory, and adhered to no opinion whatever, based upon sufficient facts to make it valuable, as to how malaria arises.

In the same case, Dr. Charles W. Chamberlain, Secretary of the Connecticut State Board of Health, and a gentleman who, from very extensive observations throughout his own State, is familiar with this subject, as far as present knowledge will allow, after admitting that he had formerly held the marsh and germ theories, acknowledged that he had recently given up both.

A similar complete change in opinion was avowed by Dr. Francis Bacon, ex-Professor of Surgery at Yale College; by Dr. N. G. Kierle, of Baltimore, Lecturer on Pathology in the College of Physicians and Surgeons of that city; by several of the principal practitioners of Berkshire County, Mass., and by a dozen well-known physicians from other portions of the country.

The vast importance of a positive or negative expression of opinion by distinguished experts upon the subject in question may be better understood when it is stated that the interests of several thousand manufactories run by water-power, in Massachusetts alone, were involved in the decision of this case, an unanimous one by the jury in favor of the mill-dam.

Although medical men with the reputation of those above mentioned find it proper to abjure long-cherished convictions, which from careful observation and logical inference have become untenable, and are forced to acknowledge themselves as ignorant of the ultimate causes of many affections as were Celsus and his cotem-

poraries eighteen centuries ago, nevertheless, the rapid strides accomplished in other branches of medical inquiry encourage us to anticipate trustfully the time when we shall be gratified with a comprehension of the invisible, mysterious, and ever-active agencies which engender the various zymotic diseases.

BENZOATE OF SODIUM IN THE TREATMENT OF ACUTE GASTRO-INTESTINAL DISEASES.

By WILLIAM P. WATSON, A.M., M.D.,

PHYSICIAN FOR DISEASES OF CHILDREN TO THE CENTRAL DISPENSARY, JERSEY CITY, N. J.

DURING the past year I have been very favorably impressed with the rapid, as well as satisfactory action of the benzoate of sodium in the treatment of acute dysentery, cholera morbus, intestinal colic, crampulous and flatulent and other allied morbid conditions of the alimentary canal.

Whether this result is due to its alkaline reaction, or to its disinfecting action on the morbid gases from the decomposing ingesta, or to its stimulating action on the liver, I will not now undertake to demonstrate. That it does give quick and permanent relief in such conditions I have carefully noted in more than twenty instances. The following typical cases are selected from my case-book:

CASE I.—*Acute Dysentery.*—Mrs. G——, aged thirty-one, usually enjoying good health, had colic, looseness of the bowels, vomiting, great thirst, and no desire for food for three or four days, and not being relieved by diarrhoea mixtures, cholera-drops, etc., sent for me. I saw her at nine o'clock in the evening, when she was suffering with severe headache; little abdominal tenderness on palpation; mouth and fauces dry; very thirsty, but retaining liquids swallowed only a few minutes, and during the last twenty-four hours complaining mostly of an unavoidable desire to go to stool, at which, however, there was only mucus and blood accompanied by violent tenesmus. Prescribed the following mixture, the dose to be repeated every half hour until relieved:

R. Sodii benzoatis,..... ʒj.
Elixirii simplicis..... ʒij.

M. S.—Two teaspoonfuls at a dose.

On the following morning she told me that soon after taking the first dose she was greatly relieved, and that she had taken only four doses when the pain and bearing down while at stool were entirely gone.

The stomach did not reject the medicine at any time, and she had not taken it since midnight, after which she rested quite well for several hours. Bowels still loose, but discharges are feculent. No tenesmus. Not much thirst. Left the following prescription:

R. Pulv. opii,..... ij. gr.
Pulv. camphor..... ʒj.

M. et in cap. iv. div.

S.—Take one capsule after each passage. To have only boiled milk and toast, and, if very thirsty, iced carbonic-acid water as the only drink.

On the following morning, I found her sitting up in bed. Said she was all right, except a little weak. No movement from bowels since six o'clock last evening. Ordered her to have half a tablespoonful of Boudault's wine of pepsin, with ten drops of the dilute nitro-muriatic acid, three times a day for one week, at the end of which she came to my office to say that she had had no further trouble.

The use of the benzoate of sodium in the above case, and in three others of a similar nature, was as surprising to me as it was gratifying to the patients. In a very few hours an attack of acute dysentery was changed to a simple diarrhoea, which yielded kindly to a few small doses of opium and camphor.

CASE II.—*Cholera Morbus.*—Mr. A——, a strong,

healthy young man, was taken at midnight, following a very indigestible dinner, with nausea and colic, soon followed by profuse vomiting and purging, which continued until five o'clock in the morning, when I found him with his knees flexed on his abdomen, which was very sensitive to pressure, face pale, pulse small, and a frequent desire to defecate. I immediately gave him fifteen grains of the benzoate of sodium in a tablespoonful of simple elixir. This was retained about fifteen minutes, when he vomited quickly, and without that very disagreeable gagging sensation in his throat which attended previous similar acts. In a few minutes he took half the quantity, when I left instructions to repeat the same every hour if required.

When I visited him again, at five o'clock in the evening, he was sitting up in bed eating poached eggs on toast. Said he was feeling all right, that he had not taken any of the medicine since eight o'clock, and was going to business in the morning. A few days later I saw him, and he told me that he had had no further trouble.

In several cases of this description the benzoate of sodium acted equally well—no other medicine being required.

CASE III.—Intestinal Colic.—In this case, representing a class in which I had usually given inhalations of chloroform or hypodermics of morphine, I was somewhat doubtful about the propriety of using the benzoate of sodium; yet, recognizing colic as due to spasms of the muscular tissue of the intestine caused by flatulency, and having seen such remarkable results from its use in analogous cases, and especially after the statement of the patient that "morphine affects my head so," I determined to use it.

Mrs. W—, aged thirty-five, anæmic, poorly nourished, occasionally has attacks of colic after any indiscretion in her diet.

When I saw her, at four o'clock in the afternoon, she was lying on her side with knees drawn up toward thorax, and frequently crying out with pain, "All over my stomach."

I learned that two or three days ago she was taken with vomiting and diarrhoea, which had been mostly relieved—the former since noon, and the latter since morning—by domestic remedies, and that she had passed no urine for twenty-four hours, during which time the paroxysms of pain had been gradually increasing in frequency and severity. She would not permit me to use the catheter, or even to carefully examine the abdomen, on account of the pain caused by any change in her position. I gave her fifteen grains of the benzoate of sodium in a tablespoonful of simple elixir, and instructions to repeat half the dose every hour if necessary. Visited her again at nine o'clock in the evening, when she told me that in a few minutes after taking the medicine she was greatly relieved; that she passed plenty of water in about one hour afterward, and did not take any more of the medicine until eight o'clock, when, having a little pain over the umbilical region, she repeated half of the first dose and had had none since. On the following morning I found that she had rested well during the night, without any recurrence of the colic. Ordered her to take, for a few days, half a tablespoonful of Boudault's wine of pepsin, with ten drops of dilute nitro-muriatic acid three times a day, and heard nothing more from her.

In the bowel complaints of children, where the passages are greenish, lumpy, mucoid, and frequently streaked with blood, I have repeatedly seen them changed to their natural color within a few hours after commencing the use of benzoate of sodium, in hourly grain doses for each year of age, and that, too, without even dieting the child.

HOW TO CURE SORE THROAT.—Mrs. Disraeli told the Queen, "When Disraeli has a sore throat I cure him by putting my arm round his neck and keeping it there all night."

EMPHYEMA — DOUBLE INCISION WITH THROUGH DRAINAGE—RECOVERY.

By M. ALLEN STARR, M.D.,

LATE HOUSE-PHYSICIAN BELLEVUE HOSPITAL, ATTENDING PHYSICIAN NEW YORK DISPENSARY.

THE methods of treatment of empyema recommended by various authorities differ widely, and the statements made by each are so positive that the practitioner is often in doubt as to which method to follow. A decision can be most readily reached by comparing the results of the various operations as they are reported from time to time. It is now acknowledged that in most cases aspiration alone will fail to relieve the condition permanently, and that a free exit must be afforded to the pus collected in the pleural cavity. It is the object of this article to recommend a double incision with through drainage, and to demonstrate its advantages over the method of a single incision. The case reported illustrates most of the points of interest to be noted:

Hannah S—, aged six, was admitted to Bellevue Hospital December 5, 1881, and assigned to the fourth medical division, Dr. H. F. Walker, attending physician. She had recovered from scarlet fever in October, but during November had suffered with headache, gastric disturbance, and general anasarca, due to a nephritis which had developed during the fever. These symptoms subsided during the latter part of November, at which time the urine increased in amount. But with the subsidence of the symptoms of nephritis a new set of symptoms developed. The child began to complain of pain in the left side, coughed a good deal without expectorating, and had a well-marked fever which was always worse at night. Her mother noticed that she could not lie on the right side, and that the left side became tender and swollen. On admission the child was thin, poorly nourished, fretful, and had a temperature of 102° ; pulse, 140; respiration, 40. The heart was displaced, its apex being in the fourth intercostal space, one-fourth inch to right of the sternum; the left side of the chest bulged outward, measuring one-half inch more than the right side in circumference at the level of the nipple, and all the physical signs of pleuritic effusion were present. Puncture with the hypodermic needle drew greenish pus. The upper level of the effusion corresponded with the space of the scapula.

On the 6th aspiration was performed, eleven ounces of pus being removed, with the result of relieving the dyspnoea, and bringing the heart apex about one inch to the left of its former position. By this procedure the level of the fluid was lowered to the seventh rib posteriorly. The child was put upon cod-liver oil and iron, and an examination of the urine having shown the presence of albumen in small amount, with a few blood-globules and hyaline and granular casts, the white drink (pot. cit. et acet. inf. digital. aq.) was ordered with a view to increasing its amount.

By the 15th the fluid had returned to the level of the spine of the scapula, though the general condition of the child had improved in spite of the hectic fever. The temperature reached 101° or 102° every night, and was not affected materially by the administration of quinine given per rectum, as it could not be retained in the stomach. During this time the daily amount of urine had increased from fifteen to thirty ounces, but it always contained albumen. Aspiration was again performed, the level of the fluid being reduced to the ninth rib by the removal of eight ounces of pus. Same treatment was continued, inf. scoparii being substituted for inf. digital. in the white drink.

On the 29th the pus had again risen to the middle of the scapula, and it was evident that the child was succumbing to the hectic fever. Her general condition was poor, she was very weak, pale, thin, and fretful; her appetite was capricious, milk being the only article of diet which was always digested; her bowels moved irregu-

larly; she passed about twenty-eight ounces of urine daily, and there was no ascites or anasarca. Aspiration having failed to afford permanent relief, Dr. Walker considered an operation necessary, and kindly intrusted it to me.

On the 30th the operation was performed under ether. All antiseptic precautions were observed, and the method of Lister was carried out in every detail. An incision was made in the seventh intercostal space, one-half inch external to the inferior angle of the scapula, with a scalpel, and a director having been introduced, the opening was enlarged with a probe-pointed bistoury until it was three-fourths of an inch in length. Through this opening forty ounces of pus was evacuated. A long probe was then introduced into the opening, and passed downward and forward to the lowest limit of the pleural cavity. Its point being felt in the ninth intercostal space, about one inch external to the mammary line, was cut down upon and brought out. A medium-sized, fenestrated, rubber drainage-tube was then attached to the probe and drawn through from the first to the second incision. Each end of the tube was secured by a safety-pin, and projected an inch from each incision. The length of the tube was about five inches. At the time of the first incision an intercostal artery was cut and considerable blood was lost. The hemorrhage was at first arrested by a serrefine, and later, as all attempts to seize the artery failed, by the introduction between the ribs of a piece of compressed carbolized sponge. Full Lister dressings were then applied.

During the operation air entered the pleural cavity at each inspiration, but as a good spray of carbolic was continuously directed upon the whole chest the possibility of sepsis was prevented. As the operation was being concluded the child's pulse, which had been growing feeble, ceased, and respiration stopped. Artificial respiration was kept up; nitrate of amyl being held to the nostrils, hypodermics of whiskey or digitalis were administered, and a hot rectal injection of whiskey and water was given. She revived slowly under the action of these stimulants, and two hours after the operation was quite comfortable, though very weak. Pulse, 120; respiration, 40; temperature, $98\frac{1}{2}^{\circ}$. Seven hours after the operation it was necessary to renew the dressings, as they were soaked with pus. This was done under the spray. During the following twenty-four hours the child's condition was critical. She slept only a few minutes at a time, vomited frequently when awake, and seemed to be growing weaker. She was nourished by milk and brandy in small amount, frequently given, both by the stomach and by the rectum. The dressings were changed once, and were found to contain considerable pus. Temperature, A.M., 98° ; P.M., 99° ; respiration, 30; pulse, 120.

On January 1st she seemed much more comfortable; did not vomit, retained milk, beef-tea, chicken soup, and brandy, and had a natural movement of the bowels. The amount of pus on the dressings was much less than before. The tube was washed through with a solution of permanganate of potash in both directions, a small amount of pus being washed out. P.M. temperature, 99° . The heart apex is now in its normal position. The child has no pain in the chest, coughs much less, and respiration is regular—30 per minute. The lung has expanded, and vesicular breathing and normal voice are heard down to the level of the seventh rib behind.

Up to January 20th the child's condition improved steadily. Her digestion was good, and she gained much flesh and strength. Her bowels moved regularly, and she passed about thirty ounces of urine daily. The chest was dressed daily with one exception, and the discharge of pus decreased steadily until only about an ounce was found on the dressing, and about a drachm was washed out. A solution of salicylic acid, one per cent., was used in washing out the tube, and the dressing was always done under the spray. The lung expanded well, and at no time was there any sacculation of pus,

the drainage being perfect. When the child sat up the discharge ran out of the anterior and inferior end of the tube, and when she lay down, the superior and posterior end being then lower, it ran in that direction. Only twice during this time did the temperature rise above 100° : once when the dressing was not renewed, and once when a small abscess formed on her left thigh.

Between January 22d and February 3d the child went through measles, having contracted it in the ward from another child. She suffered a good deal from the attendant bronchitis and laryngitis, and at one time had a temperature of 105° . During this period the discharge was very scanty, but the side was dressed daily as usual. After her recovery from measles, and until February 18th, her general condition was improving, but the discharge showed a tendency to increase, about an ounce being found on the dressing every day, and the P.M. temperature rising to $99\frac{1}{2}^{\circ}$ or 100° every night. It was thought that the heavy Lister dressing was acting as a fomentation. In place of it a light pad of oakum, bound on by a few turns of gauze was applied, and a solution of carbolic acid (one part to ninety) was substituted for the solution of salicylic acid to wash out the chest. The result was good. The temperature at once decreased at night to $98\frac{1}{2}^{\circ}$ or 99° ; the discharge became less, and on March 1st it was resolved to remove the drainage-tube. At this time the only remains of the formerly distended pleural cavity, to be found by physical examination, was a small narrow area between the two openings. The lung had expanded, and the side had slightly retracted so as to measure half an inch less than the right side in circumference, the chief deformity noticeable being the sinking of the left shoulder when she stood up. The tube was pulled through the posterior opening into the chest, being first attached to silk ligatures at its posterior extremity, so that it might be replaced if necessary. It was then pulled out of the inferior opening half an inch daily until the 6th, when it was finally removed, the discharge having entirely ceased.

On the 4th both openings had closed completely. On the 20th physical examination showed heart in normal position; slight dulness, with distant vesicular breathing, and slight diminution in voice sounds below the ninth rib behind, and below the seventh rib in the axilla on the left side. Under regular gymnastic exercise the deformity has entirely disappeared, and both shoulders are at the same level. On forcible inspiration the left side expands one-fourth inch less than the right side. The child is in good general condition, is up and plays about all day, has a good appetite, normal stools, and passes thirty ounces of urine daily, which still contains a small amount of albumen and a few hyaline and granular casts. She was discharged from the hospital, but kept under observation for three months, during which time she remained in perfect health.

In connection with this case there are several points to be noticed. It would have been well to operate at the time of the second aspiration, the result of the first aspiration showing that this means was inadequate to cure the empyema. Operation in these cases should be performed early, as the hectic fever, if allowed to go on, weakens the patient constantly.

The existence of nephritis did not seem to affect the result, and hence should not interfere with the operation. The danger of collapse is less if the pus is evacuated slowly. In this case the necessity of stopping hemorrhage prevented me from closing the posterior opening while the anterior one was being made, and allowed a too rapid escape of pus. It would be advisable to apply the dressings as soon as the operation is completed, and let the pus soak into them gradually. The drainage by means of two openings was far better than could have been secured by one alone. In this case it mattered little whether the patient was in an erect or recumbent posture, pus never collected in the cavity. This seems to be the great advantage of this method over all others.

When one has washed out a chest through one opening, and seen how a change of position of the patient will prevent or facilitate a free discharge, as the case may be, he cannot fail to appreciate the advantage of two openings, with the possibility of washing out the cavity in either of two directions. Perfect drainage is the object. It can only be secured by two openings, one of which shall be at the lowest point of the pleural cavity when the patient is standing, and the other at the lowest point when he lies down. Otherwise, during at least ten of the twenty-four hours, the drainage is imperfect, if the patient is not confined to one position in the bed. The Lister dressing is important as long as the surface liable to absorb septic matter is extensive, but when a small sinus alone remains its weight and thickness seem to make it unsuitable, and a lighter dressing favors healing. If the measles had not delayed the result three weeks, and if the light dressing had been applied two weeks earlier, it is reasonable to conclude that the drainage-tube could have been removed five weeks after the operation, instead of ten weeks, as was the case. The result of gymnastic exercise in correcting the deformity which followed the operation was very satisfactory.

It may be concluded from this case, that through drainage is eminently successful in the treatment of empyema in children, and that it has decided advantages over every other method.

Progress of Medical Science.

ARTICULAR GANGLION OF THE KNEE.—Dr. Nicaise reports, in the *Revue de Chirurgie* for June, 1883, the case of a man who presented himself for the removal of a small tumor situated upon the outer side of the knee. The tumor was the size of a small nut, somewhat flat, irregularly lobulated, soft, fluctuating at certain points, and irreducible. It was of slow growth, and slightly adherent to the skin and underlying tissues. The joint was in no way involved, and the movements of the knee were perfectly free. A positive diagnosis was not made, though the author was inclined to regard the new growth as a sebaceous cyst. When removed the tumor was found to contain a gelatinous liquid resembling the vitreous humor of the eye. The walls were irregular, presenting here and there little recesses forming a sort of secondary cysts. The inner surface was lined with flat epithelium, outside of which was a cellular shell, interwoven with elastic fibres and presenting in places a fibrous formation, due probably to irritation produced by movements of the tumor.

ACUTE SCOLIOSIS.—The following case of acute lateral curvature of the spine is related by Professor Desprès in *L'Union Médicale*, No. 54, 1883, as confirmatory of the theory of Duchenne of Boulogne concerning the nature of this affection. A young woman, twenty years of age, was attacked with typhoid fever of mild type, not accompanied by any grave cerebral symptoms, and from which she recovered in about three weeks. During convalescence her husband noticed that she did not stand as straight as before. The deviation increased gradually, without causing any pain, until she was finally led to consult M. Desprès. Examination showed a lateral curvature of the spine in the dorsal region with convexity to the left. The lumbar spine was normal, as the affection was of too recent date to permit of the formation of a compensatory curve in this region. The condition present was declared by the author to be *atrophie des spirales lombaires* on the left side. The atrophy had undoubtedly followed the typhoid fever, as it is known that muscular degeneration occurs in the course of this malady. The results of treatment were most happy, a very great amelioration being observed after only eight days. The treatment consisted in faradization

of the weakened muscles over the convexity of the curvature, repeated every day, in exercises, and in slight mechanical support. The gymnastic treatment consisted simply in trapeze exercises, or raising the body from the ground by the arms. M. Desprès does not regard apparatus as of any therapeutical value in this condition, but uses it merely as a support to be worn in the intervals of active faradic and gymnastic treatment.

**INFLAMMATION OF THE THYROID GLAND IN DIPH-
THERIA.**—Dr. Brieger relates two cases of diphtheria complicated with thyroid inflammation (*Centralblatt für Klinische Medizin*, June 23, 1883). The first case was that of a girl, eighteen years of age, who, when first seen on the seventeenth day had no fever. Two days later, while the diphtheritic membrane was still present, she had tolerably high fever with pain and swelling of the thyroid gland. There was aphonia and dyspnoea. Antiphlogistic measures proved of no avail, but considerable relief was afforded by poulticing. Twenty days later an incision was made at a point of fluctuation, and about an ounce and a half of pus evacuated. Under careful treatment the patient recovered. In the second place, that of a woman aged thirty-two, the inflammation was aborted by energetic antiphlogistic treatment and leeching in the early stage. In both cases the thyroiditis subsided before the local diphtheritic process. The author believes that the glandular inflammation was directly traceable to an invasion by the diphtheritic microbes.

ACUTE ŒDEMA OF THE GLOTTIS.—Dr. Rabère related the following case, seen by himself and Dr. Laylavoix, to the Société de Médecine et de Chirurgie (*Journal de Médecine de Bordeaux*, June 24, 1883). A man, sixty-two years of age, of vigorous health, without history of previous laryngeal trouble or syphilis, was taken with slight chills one evening after working in his garden. The next day he was a little hoarse and felt a slight soreness in swallowing, but was otherwise well. The hoarseness and difficulty in deglutition had increased the following day, and in addition there was a little dyspnoea. That evening he was suddenly awakened in a most threatening attack of suffocation. Examination showed a swelling and induration of the aryteno-epiglottidean folds, but no other trouble in the throat could be made out. Active treatment by counter-irritants, leeches, and emetics produced but slight amelioration, and upon a second attack of urgent dyspnoea it was decided to perform tracheotomy. The operation was postponed when the urgent symptoms subsided, but a third attack of complete suffocation, during the momentary absence of the attendants, resulted fatally. No cause for the œdema could be discovered, except cold, as the man had always enjoyed excellent health. There was no reason to suspect renal trouble, but unfortunately no examination of the urine was made.

FLAX AS A DRESSING FOR WOUNDS.—Dr. Makuschina writes in *Pratch*, No. 12, 1883, concerning flax as a cheap and convenient surgical dressing. She prepares it in the following way: Small bundles of flax are boiled for three hours in ordinary lye-water, and then left to soak in the same for eight or ten hours. After that it is washed five or six times in clean water, dried, and combed out. It loses about twenty-five per cent. in weight, and is a perfectly white, soft material, much more hygroscopic than before being so treated. It is several times cheaper than absorbent cotton, in Russia at least. Dr. Anton Schmidt, of Moscow (*Centralblatt für Chirurgie*, June 30, 1883), also recommends the use of flax. He says that it possesses an advantage over absorbent cotton in that it does not become matted when wet, thus retaining the secretion about the wound. By the addition of corrosive sublimate, iodoform, or carbolic acid an excellent antiseptic dressing may be prepared. In military surgery also it recommends itself by the compactness in which it may be carried, taking up much less room than either cotton or jute.

A REMARKABLE CASE OF ASCITES.—Dr. Antonio Lanini relates in *Lo Sperimentale*, vol. li., No. 1, a case of ascites occurring in a man thirty-four years of age, in which paracentesis was performed ninety-two times from April, 1878, to December, 1882. During this period over three hundred and eighty gallons of fluid were withdrawn from the abdominal cavity without any apparent loss of strength on the part of the patient. The cause of the ascites was not clear, for careful examinations made immediately after the removal of the fluid could detect nothing abnormal in the abdomen. There were no signs of obstruction to the portal circulation, and the normally secreted urine contained no albumen. The author thinks that there was an irritable condition of the peritoneum, resulting from an inflammation of this membrane, from which the patient suffered in 1878. There had never been any fever since the subsidence of the peritonitis. Diuretics, cathartics, counter-irritation, diaphoretics, strong compression of the abdomen, all were tried without success. This patient was related to another man, also under Dr. Lanini's care, on whom in the course of twenty years phlebotomy had been performed five hundred times, and cupping thirty times, besides the application in the intervals of two thousand leeches.

PERITONITIS AND PERITONISM.—In observing a case of acute peritonitis, rapidly fatal, in a young man who had swallowed some orange-pits, Professor Trastour recalled the distinction established by Gubler in 1877 between peritonitis and peritonism. By the latter term is meant the totality of grave reflex phenomena sometimes observed in a patient suffering from peritonitis. These symptoms are produced through the agency of the great sympathetic, and are often overwhelming in their violence. Peritonism is not dependent upon the intensity of the original inflammation. A light peritonitis may be the occasion of the violent symptoms of peritonism, while, on the other hand, an extensive purulent inflammation of the peritoneum may give rise to no general reflex phenomena. The treatment of peritonism consists in the administration of alcohol, chloral, and especially of opium in large doses. The latter may be given in fractional doses, aggregating fifteen grains in the twenty-four hours, its effects, of course, being most carefully watched.—*Revue Médicale*, June 23, 1883.

PERISPLENITIS AND PLEURISY IN TYPHOID FEVER.—Simple pleurisy, without pulmonary lesion, is supposed to be a rare complication of typhoid fever. Guillermet has collected a number of such cases, and seems to agree with another observer who regards simple pleurisy as rather common in typhoid fever, and who attributes it to the marked tendency to serous inflammation which exists in this disease. The observations of Dr. Merklen (*Revue Médicale*, June 23, 1883) lead him to advance a more rational pathogenesis. He states that the spleen in typhoid fever is not only the seat of a passive congestion, but is also a centre of inflammatory irritation which may involve the capsule. This may determine by continuity a localized or general peritonitis, whence the inflammation may spread to the diaphragmatic pleura. In this way he would explain the origin of simple pleurisy, and not by a preference of inflammation to seek the serous membranes.

TYPHOID FEVER AND PREGNANCY.—Dr. Martinet concludes a paper with this title as follows: 1. Typhoid fever is rare in pregnant women. 2. It determines abortion in about one-half of the cases; the more surely, the less advanced is the pregnancy. 3. The lightest forms may produce abortion. 4. This complication arises usually in the course of the third week, and sometimes at the beginning of convalescence; it causes no recrudescence nor return of fever. 5. Puerperal accidents are the exception. 6. The immediate causes of abortion are unknown; elevated temperature, active or passive,

uterine congestion, and changes in the blood, although seemingly the most probable, cannot be regarded as the causes in all cases. 7. The treatment for the fever and the miscarriage is the same as for each condition alone. *L'Union Médicale*, Nos. 52 and 53, 1883.

POISONING FROM DISEASED MEAT.—Dr. Ruysch reports the poisoning of about two hundred persons in the town of Heesch, Holland, who had eaten the flesh of a cow that had died in giving birth to a calf, also the flesh of the still-born calf and of another dead calf. All who had eaten the meat were taken ill and three died. They suffered from severe gastric symptoms, chills, fever, headache, and great depression, so that the physicians supposed at first that they had to do with an epidemic of typhoid fever. Others presented the symptoms merely of gastro-enteritis. The nature of the poison in the flesh could not be clearly determined, as none of the animals had died from an infectious disease.—*Centralbl. für Klin. Med.*, June 9, 1883.

A HITHERTO UNDESCRIBED NEUROSIS.—Dr. Wernicke relates the case of a man, twenty-five years of age, who suffered from tonic spasms of the voluntary muscles (*Centralbl. für Klin. Med.*, June 9, 1883). The affection differed from tetanus in that each convulsion was of shorter duration, the contractions were weaker, and the spasms did not involve the entire body but only single groups of muscles at a time. The convulsions were painless and recurred at frequent intervals, but ceased during sleep. They involved the muscles of respiration, but left free the upper extremities and the territory supplied by the cranial nerves with the exception of the right platysma myoides muscle. The patient had a club-foot from a spastic contraction of the left gastrocnemius muscle of fifteen years' standing, otherwise all the functions of body and mind were normal. No cause for this affection was determinable. The only remedy which had produced even a temporary amelioration was curare. The convulsions, slight in the beginning, had gradually increased in intensity and in the number of muscles involved. The author regarded the tonicity of the convulsions as indicating a spinal origin, since cerebral spasms are of a mixed tonic and clonic character, as in epilepsy. As to the question whether this slowly progressive disease was dependent upon a palpable lesion of the cord (sclerosis), or whether it was a disease in which the changes in the cord were unrecognizable by any means yet at our disposal, he declared for the latter, and designated it as a neurosis. Two brothers of the patient suffered from a similar complaint. The father had had syphilis.

THE TREATMENT OF BASEDOW'S DISEASE.—From an experience in upward of seventy cases, and fortified by the unanimous observations of Von Dusch, Eulenburg, Meyer, Erb, and others, Dr. Chvostek is led to regard the rational employment of galvanism as the most important part of the treatment of Basedow's disease. He recommends the following method to be pursued: 1, the ascending constant current applied to the cervical sympathetic, on each side, for at the most one minute; 2, the same to the spinal cord (the anode at about the fifth dorsal spine, the cathode high up in the cervical region); 3, through the occiput (one pole at each mastoid process), and in certain cases also through the temples, a constant current, for at the longest one minute, and so weak that the patient can feel but the slightest sensation of burning. Sometimes also local galvanization of the thyroid gland with a weak constant current for about four minutes, the current to be reversed at the end of each minute. The applications should be made every day if possible. As a rule very good results were obtained, even in the most severe cases a cure or marked improvement being recorded. In three cases death resulted from excessive anæmia or complications.—*Centralbl. für Klin. Med.*, June 23, 1883.

A LOUD-SOUNDING HEART MURMUR.—Dr. Herman Tittinger describes a peculiar murmur, characterized by the distance at which it is audible (it can be distinctly heard through the bed-coverings), by its stability (it is but slightly influenced by the intensity of the heart's action), and by its character (it is composed of both a primary and an accessory sound). Together with the murmur is perceived a widely propagated tremor. This phenomenon occurs only with rupture of the valves or of the chordæ tendinæ in immediate connection with them. The primary murmur is caused by insufficiency of the valves, the secondary sound by the flapping of the loose valves and chordæ tendinæ in the returning blood-stream. A diastolic murmur indicates a rupture of the semilunar valves, while a systolic sound points to the (much less frequent) lesion of the mitral valve.—*Centralbl. für Klin. Med.*, June 9, 1883.

EPILEPSY CAUSED BY INTESTINAL WORMS.—The following case is reported by Dr. Windelschmidt in the *Allgem. Med. Central-Zeitung* of June 9, 1883. A woman, forty years of age, had suffered for six years from convulsions, epileptic in character, which were steadily increasing in frequency, until finally the attacks appeared every evening as soon as she lay down, lasting several hours and returning again toward morning. Upon questioning it was ascertained that she was troubled with large numbers of ascarides in the rectum and vagina. Vaginal and rectal injections of a bichloride of mercury solution were ordered, and in five days the attacks had wholly ceased. They returned once again upon the re-appearance of the worms, but ceased after a few injections, and have never since troubled her.

CYSTIC TUMORS OF THE TONGUE.—Dr. Gêhe divides lingual cysts into four varieties, viz.: serous, mucous, hydatid, and dermoid cysts. The serous tumors are situated ordinarily on the under surface and at the base of the tongue. They contain a clear, transparent fluid, and are lined upon their inner surface with pavement epithelium. The mucous cysts are found in the situation of the mucous glands, at the tip, sides, and between the tonsils. They contain a stringy fluid with crystals of cholesterin. Hydatid cysts (cysticerci, echinococci) are developed in any part of the tongue. Dermoid cysts are very rare and are always found in the median line of the organ. These are formed by a pushing forward of the blastoderm through the branchial fissure. Serous cysts arise from erectile tumors or from retained secretion. Mucous tumors are of inflammatory origin caused by myxangitis leading to partial obliteration of the ducts. Severe symptoms arise only from inflammation of the sac. Hydatid tumors are the only ones that attain any considerable size, the others remain small and only interfere slightly with speech and mastication. They are always chronic in their course. The treatment of all forms of lingual cysts is the same. It consists either in transfixion by a piece of silk, which is left *in situ* and causes suppuration, in puncture, with or without subsequent injection of an irritating fluid, or in partial or total extirpation. Dr. Gêhe prefers the latter procedure as being the least likely to cause trouble and the most radical.—*Centralbl. für Chirurgie*, June 23, 1883.

THE CLAY-COLORED STOOLS IN JAUNDICE.—Professor Gerhardt states that the clay-colored stools in icterus contain a great number of needle-shaped crystals arranged in bundles. Sometimes the quantity of crystals is so great that the fecal mass seems to be in great part made up of them. Their shape is suggestive of tyrosin, but mixed with the needle-shaped crystals here and there are little spheres resembling leucin. The feces, when stirred up with water, settle in four layers. The upper layer is thin, milk-white, and consists almost wholly of fat drops. The three other layers (flaky, watery, and sedimentitious) contain the crystals in nearly equal pro-

portion. Some of the clinical tests also show the presence of tyrosin. Since only colorless stools contain these crystals, there can be no doubt that their presence is in some way connected with icterus. But whether it is due to the continued action of the gastric juice in the intestines, or to the action or non-action of the pancreatic juice without the addition of bile, or whether it is a result of the decomposition of the ingesta in the intestine, are questions which the author leaves unanswered. He also suggests, without deciding the question, that this quantity of tyrosin in the intestine may be accountable for the appearance of the same substance in the urine. The white or whitish gray color of the stools proceeds from the presence of either fat or these tyrosin crystals.—*Deutsche Medicinal-Zeitung*, July 5, 1883.

TREATMENT OF WOUNDS OF THE BLADDER.—Dr. Juliard had the misfortune to make a rent nearly five inches long in the posterior wall of the bladder, while breaking up adhesions during an ovariectomy. Fifteen sutures were inserted, and the wound healed by first intention. The two serous surfaces were brought into apposition, care being taken not to include the mucous membrane, so as to avoid infiltration of urine alongside the threads into the connective tissue. Cat-gut sutures were employed, and a catheter was left in the bladder, so as to ensure perfect drainage of urine, and thus avoid any stretching asunder of the edges of the wound.—*Centralblatt für Gynäkologie*, July 7, 1883.

TREATMENT OF ERYSIPELAS.—In four cases of erysipelas Dr. Bogusch employed hypodermic injections of resorcin in a five per cent. aqueous solution. The injections were made along the border of the erysipelatous part, at a distance of about three lines from each other, the point of the needle being directed toward the diseased spot. In each case from thirty to seventy injections were made, and no other treatment was resorted to. The temperature fell rapidly and the spread of the disease was arrested. Dr. Tusbin employed hypodermics of bichlorhydrate of quinine in five cases of erysipelas. One or two injections sufficed. The reddened parts were painted with camphorated and carbolized oil. He never observed any ill effects to follow the injections, though others have reported numerous abscesses and indurations. This double salt of quinine, apart from its great solubility, is therapeutically in no way superior to the sulphate.—*Lyon Médical*, June 17, 1883.

DIETETIC TREATMENT OF NUTRITIVE DISORDERS IN INFANTS.—Dr. Biedert has treated a number of cases of infantile digestive disorders without drugs, by means of a strict regulation of the diet. The diseases thus treated were dyspepsia and dyspeptic diarrhoea, chronic catarrh, extreme atrophy (tabes mesenterica), ulcerative enteritis, cholera infantum, and one case of supposed epidemic dysentery. The children were most carefully watched, and the greatest care observed in carrying out the minute details of treatment. From the results obtained the author feels himself justified in recording the following deductions (*Centralblatt für Klinische Medizin*, June 16, 1883): 1. A surprisingly large number of gastro-enteric disorders in infants stand in such close relation with the quality and insufficient quantity of food, that the diseases, even in the most serious cases, may be cured solely by the administration of a suitable diet. 2. The quantity of food given is of the greatest moment. 3. The nourishment must often be given in greatly diluted form. 4. The proportion of albumen to fat plays an important rôle. The digestion of albumen is facilitated by mixing it with a much larger proportion of emulsified fat than is found in cow's milk—that contained in human milk being the proper amount. 5. It should not be forgotten that at times there is a diminished absorption of fat, in which case it should be greatly reduced in amount, or, in order not to interfere with the digestion of albumen, slightly reduced to a proportion midway between that of human milk and cow's milk.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 18, 1883.

PROGRESS IN THE REGULATION OF MEDICAL PRACTICE.

THE reports of the quarterly meetings of the Illinois State Board of Health generally furnish some interesting reading. The last report, covering the meeting of June 29, was no exception; and we give here some of the facts which were there presented, since they have much more than a local interest.

It appears that during the last quarter, certificates to practise medicine and surgery have been given to one hundred and ninety-two persons, while twenty-eight applications were refused. These latter applications were chiefly from "cancer-doctors" and from "natural physicians," one of whom wished "to travel through several States in order to cure their diseases, such as tape-worms, diseases of the stomach, skin, etc."

The secretary states that the resolution previously made to recognize the diplomas of the Indiana Eclectic College is likely to be revoked, owing to doubts about that college's honesty.

Measures are being adopted for the securing one common Examining Board on preliminary education for all the medical schools of Chicago. This would be a step forward which is to be greatly desired, and which should be attempted in other States.

An effort was made during the past quarter to secure the passage of a law which would get rid of advertising and lecturing quacks. The following bill was drawn up, and we insert it here:

"1. *Be it enacted:* That it shall be unlawful for any person or persons, professing to heal the sick or to remove deformities, to publish or otherwise set forth in the State of Illinois their powers, promises, or claims by any advertisement, card, circular, hand-bill, pamphlet, book, writing or lecture in the manner usual to the chronic or private disease specialist, or to solicit practice by agents or otherwise, in any but the ordinary methods of reputable physicians.

"2. That it shall be unlawful for any person or persons to furnish or sell, or to advertise for sale, any instrument, appliance, apparatus, drug, nostrum, operation, or other device, for the prevention of conception, for the procuring of abortion, or for any other criminal or immoral purpose.

"3. That each and every violation of this act, in any of its provisions, shall be punished by a fine of not less than fifty dollars nor more than five hundred dollars, or by imprisonment in a county jail for a period of not less

than thirty days nor more than three hundred and sixty-five days, or by both such fine and imprisonment."

The bill passed to its second reading, and would probably have become a law if the Legislature had not adjourned sooner than was expected.

The class of persons whom it was intended to affect is well shown by the specimen letter which the secretary received from a correspondent in Farina, Ill.:

"Sir—Our village was visited a few days ago by a 'specialist' from Indiana calling himself Dr. Pickett. He came here to sell 'marriage guides,' etc., and to give private lectures. He was also a pretended phrenologist and gave charts. His private lectures were given to men and women separately, and in his last lecture he offered for sale a recipe or appliance of some kind which he warranted to 'prevent conception.'"

Dr. Rauch also reports the unearthing of another diploma mill. It is situated in the beautiful city of Milwaukee, Wis., and is called the "Milwaukee College of Medicine and Surgery." It claims to be legally incorporated, but it grants diplomas after attendance upon one course of lectures.

The report concludes with various facts regarding the existence and prevention of contagious diseases in the State.

HOW TO MAKE PHOTOGRAPHS EASILY AND CHEAPLY.

UNTIL recently medical men who wished to have a pictorial record of important cases were to a greater or less degree prevented by personal inability, or incidental inconveniences.¹ Photography by means of the "dry plate" has placed within the reach of the profession the means of securing a picture of any case, and this with but small outlay for apparatus and materials.

An outfit for taking photographs four by five inches can be purchased for ten dollars, and by substituting an imitation Dallmeyer lens for that of the outfit the expense need not much exceed fifteen dollars.

With such an apparatus pictures can be obtained amply sufficient for the record of cases.

Dry plates can be bought by the dozen, kept for any length of time before and after exposure, and developed at leisure.

A dark room for developing the plates can be extemporized by any dark closet, or in default of that, the operation can be performed by night. The light in the dark room must be non-actinic, and is secured by a lantern with red glass.

Photographic dealers supply a small manual giving all of the details. They are, in brief, as follows: The case is properly focussed on the ground glass of the camera, which is then replaced by a slide containing the plate.

The lens is uncapped for a few seconds, and as far as the patient is concerned the process is finished. At this stage the dry plate may be sent to a photographer for development and printing; but if not, and preferably not, it is taken to the dark room, placed in a pan, and a solution of oxalate of iron poured over it. When the picture comes out sufficiently, it is washed with a few changes of water and placed in another pan containing hyposulphite of soda.

¹ How to Make Photographs: a Manual for Amateurs. By T. C. Roche, edited by H. T. Anthony. Illustrated. New York: E. & H. T. Anthony, & Co., 591 Broadway. 1883.

The hyposulphite dissolves off the undecomposed bromide of silver, and "fixes" or renders permanent the image. The negative thus produced will yield an indefinite number of pictures by the printing process.

PRINTING.—Silver : A strip of sensitized silver paper is placed on the negative in a printing frame and exposed to the light. It is then soaked in a solution of chloride of gold, or "toned," and finally "fixed" by placing it for a few minutes in hyposulphite of soda solution. It then appears as the conventional photograph. Cyanotypes, or blue prints, will serve for many purposes as well as silver prints, and can be made much easier. Any paper can be coated with a solution containing one part of ammonia citrate of iron, one part red prussiate of potash, and eight of water, dried and exposed as in the former case. The resulting print need only be soaked in plain water, when it appears as a bright blue.

Glass positives or transparencies are made by exposure in the printing frame and developed in a manner similar to the dry plates. They can then be used in the magic-lantern. It is important in photographing a case to have the subject properly lighted. This can best be done by placing the sitter at a window having a full view of the sky. There will then be too high a light on the window side. But by means of a sheet of white wrapping paper as a reflector, the light can be so proportioned as to make an exceedingly good picture.

Micro-photography.—Some excellent micro-photographs have been made by medical men. The same principles are involved in their production as in the ordinary photograph. The source of light may be a kerosene lamp, so arranged as to illuminate the microscopic slide by means of a bull's-eye condenser. Those who are interested in the subject can find an excellent article by Dr. R. L. Maddox, in *The British Journal of Photography Almanac* for 1883.

There yet remains an interesting point to consider in regard to the subject of photography by medical men, and that is as a recreation.

It can be asserted with confidence that there are few pursuits which may yield more agreeable recreation to the average professional man than the practice of photography. There is a peculiar fascination in placing the white exposed plate in the developing pan and watching the picture resolve itself out of nothing. It is akin to magic and loses nothing of its interest by repetition. By means of instantaneous plates the infant smile can be registered, and thus the personal interest of the operator can be extended to other members of the family. Country practitioners and those spending vacations in the country can bring back with them any pleasing landscape that may come under their observation.

It may be said, finally, that photographic amateurs as a rule never lose their interest, mainly for the reason that there are so many unsolved subjects which offer means of unlimited study.

WATER FOR INFANTS.

With the exception of tuberculosis, no disease is so fatal in infancy as the intestinal catarrh of infancy, occurring especially during the hot summer months, and caused, in the great majority of cases, by improper diet. There are many upon whom the idea does not seem to

have impressed itself that an infant can be thirsty without, at the same time, being hungry. When milk, the chief food of infants, is given in excess, acid fermentation results, causing vomiting, diarrhoea, with passage of green or greenish-yellow stools, elevated temperature, and the subsequent train of symptoms which are too familiar to need repetition. The same thing would occur in an adult if drenched with milk. The infant needs, not food, but drink. The recommendations of some writers, that barley-water or gum-water be given to the little patients in these cases, is sufficient explanation of their want of success in treating this affection. Pure water is perfectly innocuous to infants, and it is difficult to conceive how the seeming prejudice against it ever arose. Any one who has ever noticed the avidity with which a fretful sick infant drinks water, and marks the early abatement of febrile and other symptoms, will be convinced that water, as a beverage, a quencher of thirst, as a physiological necessity, in fact, should not be denied to the helpless members of society. We have often seen an infant which had been dosed *ad nauseum* for gastro-intestinal irritability, assume, almost at once, a more cheerful appearance and rapidly grow better when treated to the much needed draught of water. If any one prescription is valuable enough to be used as routine practice it is—"Give the babies water."

HABITUAL NOSE-BLEEDING AND ITS TREATMENT.

CLINICALLY we may classify attacks of nose-bleeding under three heads: There are, first, the accidental and incidental attacks, which are common to all; second, there are the frequent and severe attacks which are liable to occur in cases of hæmalophilia, leucæmia, scurvy, morbus maculosus, etc., and in local disturbances where there are polypi, vascular hypertrophies, etc. But, besides these, there are cases, and every practitioner sees them, where the patient suffers for years from attacks of nose-bleed, and where no especial constitutional or local cause seems to be present. A number of German observers have been studying this condition, and recently Dr. O. Chiari gives in the *Wiener Medicinische Zeitung* a summary of their opinions, with some conclusions of his own. These latter are founded upon considerable personal study and have a practical bearing, so that we venture to present them here. Dr. Chiari believes that in most cases of what he terms "habitual nose-bleed," not dependent on injuries, catarrhs, polypi, etc., the hemorrhage comes from a circumscribed locality in the nose, which can generally be seen and reached. He has studied the history of twelve cases of nose-bleed, nine of the patients male and three female; most of them were young, the age varying between fifteen and twenty years. All had suffered from epistaxis for a series of years. The attacks occurred sometimes daily for a period, in other cases weekly or monthly. They differed in violence; in some cases being slight, in others alarmingly persistent. All the patients suffered from their trouble, there being such symptoms as headache, weakness, anemia, mental annoyance, etc. The attacks were sometimes brought on by sneezing, blowing the nose, or slight mechanical violence; but oftener they occurred spontaneously, and sometimes even during sleep. In two cases only did the hemorrhage come from both nostrils.

Now Chiari states that in all his cases the source of the bleeding was a circumscribed spot, generally about the size of a millet-seed, which could be seen on the cartilaginous septum near its junction with the bony septum. By pressure upon this point bleeding could be stopped. He directed treatment to this point alone, applying generally the galvano-cautery, but sometimes the lunar caustic. Five cases were cured positively; five more did not return to his clinic; two were improved.

The position of the bleeding-point upon the nasal septum was confirmed by Hartmann's observations, and Chiari states that in twenty-two out of twenty-five observations it was found there. The ease with which the hemorrhage is controlled by properly applied compression, and the possibility of curing the trouble, make the observations of Chiari of especial interest.

DR. RUSSEL'S PAPER ON MALARIA.

WITHIN a few years malaria has become a bugbear, so to speak, in the Middle and Eastern States. Unlike other zymotic troubles in our vicinity, it is always with us on Manhattan Island and its surrounding regions. But its gradual and uninterrupted march into Connecticut and Massachusetts of late years, with entire disregard for those local conditions formerly considered as essential factors in its development, has led to renewed investigations into its causes and peculiarities. Therefore every contribution to such studies must possess a special value.

For this reason we call attention to the article by Dr. Charles P. Russel in the present number of *THE MEDICAL RECORD*. Dr. Russell is well recognized as an authority in matters of vital statistics, hygiene, and public health, and his views upon so interesting a branch of these subjects should command attention, notwithstanding that they seem to be in conflict with the traditional ideas of the profession, and even with the important discoveries, alleged to have been made more lately, of specific disease-germs.

Without in any manner endorsing Dr. Russel's opinions, we must acknowledge that they are supported by those of many other well-known medical men.

THE VICTIM OF IRREGULAR PRACTICE.—An inquest was held, July 26th, in the case of a woman who had died suddenly on July 17th. The jury found that death resulted from septicæmia, and expressed the opinion that it is the duty of the authorities to protect the public against unauthorized practitioners of medicine. Deceased was attended by Edward R. Duffy, who has had considerable practice but who calls himself a student of medicine. Duffy is not registered with the Health Department.

OBSTETRIC PROGRESS.—In a discussion by the Obstetrical Society of Washington on the induction of premature labor, one of the speakers remarked that he had heard a professor of obstetrics tell his class that he "believed the time would come when fashionable women would have their children at any time that suited their convenience during the last four weeks of pregnancy." What will the fossils who used to maintain that there was such a thing as "meddlesome midwifery" say to this?—*Obstetric Gazette*.

News of the Week.

THE CHOLERA AND YELLOW FEVER.—The meagre reports received at Washington during the past week would indicate that neither yellow fever nor cholera has made any progress toward obtaining a footing in the United States since our last issue of *THE RECORD*. The two yellow-fever ships in quarantine at the Capes—"Cape Charles quarantine station"—are reported by Surgeon Henry Smith, of the Marine Hospital Service, as clean and free from disease, the Andean ready to take on a cargo, and the California only waiting for supplies before sailing for Liverpool. There are no infected vessels at the Pensacola or Mississippi quarantine stations, all such vessels having been sent to Ship Island, where they are undergoing the cleansing process necessary for their purification. The reported escape of two men from Ship Island has been officially denied, Passed-Assistant-Surgeon John Godfrey stating that they were from Cat Island and had never been in quarantine at that station. In fact, the crews of all vessels in quarantine, as well as all employees of the various stations, are mustered twice each day, so that escapes are difficult and would be discovered in a few hours. Before ships are permitted to leave quarantine their masters are furnished with a "discharge certificate" as follows:

"This is to certify that.....has been discharged from quarantine with permission to proceed to sea or port of destination. In my professional opinion no danger need be apprehended in allowing said vessel to discharge her cargo or ballast and reload for sea. But in no case will this certificate be held to allow the entry of any vessel until after examination and permission of the local quarantine authorities.

.....
Surgeon U. S. M. H. S., in charge.

A weekly report of vessels remaining, arriving at, and departing from the various quarantine stations is made to the Surgeon-General. This report gives the name of the vessel, date of arrival, where from, destination, cargo, condition of vessel, condition of cargo, number and sanitary condition of crew, number and sanitary condition of passengers, disease, number of cases, number of deaths, treatment of vessel and cargo at quarantine, date of departure of vessel from quarantine, and remarks. This report is signed by the officer in charge and forwarded weekly to the Surgeon-General's office. At foreign ports the sanitary inspectors, in addition to forwarding cable messages upon the departure of infected or suspected vessels, are required to send weekly abstracts of bills of health issued to all vessels bound to United States ports. These abstracts show the number of bill of health, date, name of vessel and rig, destination, sanitary condition of vessel, sanitary condition of cargo, sanitary condition of crew, sanitary condition of passengers, sanitary condition of port, and remarks. Under "remarks" a statement is made whether vessel had been at an infected dock, number of hours or days in port, and such other facts as may be of importance. At the bottom of the blank are spaces for showing the number of deaths from yellow fever, cholera, and small-pox during the week. This blank is

signed by the sanitary inspector of the Marine Hospital Service and forwarded weekly to the Surgeon-General.

Despatches from Vera Cruz of the 3d inst. state that the steamship City of Puebla sailed from that port for New York, and the steamship Statesman for Brazos on that day. Also despatch from Havana the 6th gives notice that the steamer Amethyst left four cases of yellow fever at that port, and sailed for Boston on the 4th. A barque arrived at Washington docks, Sunday last, direct from Trinidad, but had no sickness on board. She was spoken at the mouth of the Chesapeake, down at the Capes, and permitted to come up, as she was healthy and loaded with asphalt.

The Consul-General at Cairo, Egypt, in an official letter to the Secretary of State under date of July 5, 1883, reports that cholera had broken out in a few adjacent towns, the fact being first made public on June 20th, when it prevailed so extensively in the town of Damietta, a place of thirty-five thousand inhabitants, that concealment was no longer possible. The disease was officially pronounced true Asiatic cholera, but its source unknown. The general belief among the more intelligent citizens, including many physicians, was that it originated in Damietta, and resulted from the lack of proper sanitary regulations in that province. It appears that many cattle have been dying of late with a disease resembling epizootic; that their carcasses were thrown into the Nile and adjacent canals leading into it; that the poor people fed upon these diseased animals and unripe fruit, and that cholera broke out among them from this cause. He further states that the towns of Mansura, Serbin, and Samanoud are similarly afflicted, but that the Egyptian Government is actively engaged in staying the epidemic by establishing sanitary cordons about the infected districts by competent officials, with every hope of arresting the disease.

On the other hand, the Consul at Smyrna, under date of July 13th. claims that the disease in Damietta is not Asiatic cholera, but is some other disease and is due to the unsanitary condition of the province. Be this as it may, the fact that it is not confined to Damietta, that it is gradually extending its area, and that the well-fed, well-cared-for British troops are among the sufferers, gives us every reason to regard the disease as a dangerous visitor and one that should be kept out of the country.

A letter from C. E. O'Hara, treasurer of the "Seymour Paper Co.," of New York, was received by Surgeon-General Hamilton recently, saying, "The problem with us is the future of the Alexandria (Egypt) rag business. We shall buy no rags for a long time to come, but what is the limit of time when it will be safe to move the rags to a market. An opinion from you on this point would be valuable, but I presume you are not prepared to give it. I have thought the matter over and can see no light. It may be of interest to you to know that five thousand to six thousand *tons* of rags are exported annually from Egypt, and nearly all come to the United States. . . . Of course all these rags must be put under the ban because a small portion, perhaps a ton, may be infected. If there is no outlet for them, most of them will be saved until the markets are open, and why not the infected with the others? The true remedy would be for the Egyptian Government to have the entire stock burned

(paying for them first); but they won't do this, as it will benefit only the people of other countries, we may say England and the United States only, no other nations using more rags than they produce."

Surgeon-General Hamilton suggested dumping all rags into chlorine vats at Alexandria, before shipment, this of course would necessitate the presence of a trusted officer of this Government to see that the work was properly done. It is obvious no limit of time could be fixed when rags gathered in an infected country could be safely received into the United States.

Obituary.

JACOB S. MOSHER, M.D.,

ALBANY, N. Y. 2

DR. JACOB S. MOSHER, a distinguished physician of Albany, N. Y., was found dead in his bed on Monday morning last. Around him lay books and papers, and the lamp above his head was still burning. Death was evidently sudden, painless, and without a struggle.

He was born in Coeymans, March 19, 1834. He graduated at Rutgers College in 1853, and had the degree of Master of Arts from that Institution. He entered the Albany Medical College, from which he received the degree of Doctor of Medicine in 1863. Early in the ensuing year he entered the corps of volunteer surgeons for New York troops, and was attached to the Army of the Potomac as it lay before Petersburg. He was subsequently made Assistant State Medical Director of the State of New York, and went on duty at Washington. From 1869 to 1873 he was Surgeon-General on the staff of Governor Hoffman. Since graduating, Dr. Mosher settled at Albany, where he practised, except from 1870 to 1876, during which time he was Deputy Health Officer of the port of New York, first under Dr. Carnochan, and afterward under Dr. Vanderpoel. At the expiration of his term of office he spent a short time in England. Then he returned to Albany, and since that time has attended to a large and remunerative practice. He became a valued member of the Albany County Medical Society, and was its President prior to Dr. N. L. Snow, the present incumbent.

In the hospitals of Albany he was a faithful worker. So, too, it was with the Albany Medical College, of which for several years he was the right-hand man. He was Dean of the College of Pharmacy, of which he was one of the originators, and was President of the Alumni of the Albany Medical College.

Since 1866 he has been a member of the Board of Trustees of the State Normal School, and has fulfilled his duties with his usual care and thoroughness. He was also a Trustee of the Albany Female Academy. In 1878 or '79 he was President of the Young Men's Association. At the time of his death he was President of the Local Board of Health.

Dr. Mosher was literary in his tastes and had collected a fine library. His fancy ran toward engravings and etchings, of which he had a great many, and his judgment in regard to them was considered excellent. One of his "hobbies," as he once told the writer, was epics, and of the great religious poems of all ages and all countries he sought to have the best and choicest editions. In every respect he was a man of culture and refinement.

Dr. Mosher was married December 30, 1863, to Emma S., daughter of Jesse Montgomery, of this city. She died in 1879, leaving four sons and one daughter, who survive their parents. The oldest, "Monte," as he is called, is a student in Union College.

Dr. Mosher was a member of St. Paul's Episcopal Church, a member of the Alpha Beta Kappa Society, and also ranked high in the Masonic Order, belonging to Master's Lodge No. 5.

Reviews and Notices.

A PRACTICAL TREATISE ON IMPOTENCE, STERILITY, AND ALLIED DISORDERS OF THE MALE SEXUAL ORGANS. By SAMUEL W. GROSS, A.M., M.D., Professor of the Principles of Surgery and Clinical Surgery in the Jefferson Medical College, etc., etc. Second Edition, thoroughly revised. With sixteen Illustrations. 8vo, pp. 176. Philadelphia: Henry C. Lea's Son & Co. 1883.

DR. GROSS has been so long known to the profession that this little work will derive value from the high standing of the author, aside from the fact of its passing so rapidly into its second edition. This is indeed a book that every physician will be glad to place in his library, to be read with profit to himself and, it may be, with incalculable benefit to the patient. Besides the subjects embraced in the title, and which are treated of in their various forms and degrees, spermatorrhœa and prostatorrhœa are also fully considered. In regard to impotence and spermatorrhœa, usually ascribed to functional causes, the author considers these affections as due to reflex disturbances of the genito-spinal centre, and that they are almost invariably dependent upon some lesion of the prostatic urethra. The work is, moreover, thoroughly practical in character, and will be especially useful to the general practitioner.

HANDBOOK FOR HOSPITALS. By the State Charities Aid Association. 12mo, pp. 263. New York: G. P. Putnam's Sons. 1883.

THE present is the second edition of the above work, carefully revised and enlarged, in which all the general and internal minutiae essential to hospital management and discipline, viz., the care of the sick, of the insane, the institution itself, hygiene, disinfection, pauperism, the distribution of public funds, and the establishment of village hospitals and of isolated cottages for infectious cases are presented, not only with completeness but with interesting detail, which will prove of service to all—the public at large as well as to the profession—who are either directly or indirectly interested or engaged in hospital work.

A TREATISE ON THE DISEASES OF THE EYE. By J. SOELBERG WELLS, F.R.C.S., Doctor of Medicine of the University of Edinburgh; Professor of Ophthalmology in King's College, London, etc., etc. Fourth American from the Third English Edition, with copious additions. Edited by Charles Stedman Bull, A.M., M.D., Lecturer on Ophthalmology in the Bellevue Hospital Medical College; Surgeon to the New York Eye and Ear Infirmary, etc. Illustrated with two hundred and fifty-seven engravings and six colored plates. Together with selections from the test types of Professor E. Jaeger and Professor H. Snellen. 8vo, pp. 846. Philadelphia: Henry C. Lea's Son & Co. 1883.

THE work of Dr. Wells is so well known throughout the medical profession, that it scarcely needs especial commendation. The present edition appears in less than three years since the publication of the last American edition, and although the original text is not very materially altered, yet, from the numerous recent investigations that have been made in this branch of medicine, many changes and additions have been required to meet the present scope of knowledge upon this subject. Hence it may be well to mention in what respect this edition differs from its predecessor. The chapter on Diseases of the Lids is augmented by descriptions of Landolt's Method of Blepharoplasty, and by the editor's Method of Treatment of Depressed Scars of the Face. In Diseases of the Conjunctiva, an entirely new section on Purulent Conjunctivitis of New-born Children has been added, together with one on Membranous Conjunctivitis. Diphtheritic Conjunctivitis is also greatly increased by the addition of new matter. Sattler's views on the nature

of Trachoma have also been added to the section on Chronic Granular Conjunctivitis. Under Diseases of the Iris and Ciliary Body, a new section has been inserted on the Comparative Physiological and Therapeutical Value of Mydriatics. The chapter on Sympathetic Ophthalmia has been enlarged, containing the discussion before the London International Medical Congress as to the seat of the lesion being in the optic nerve, together with the views of Mooren on the same topic; also additional notes upon the value of Optico-ciliary Neurotomy. The opinions of Priestley Smith and Brailey upon the Nature and Causes of Glaucoma have been embodied in the chapter on that subject. In the chapter on Diseases of the Vitreous Humor, the value of the magnet in the removal of particles of steel or iron from the eye receives greater consideration. The recent observations of Hughlings-Jackson on Optic Neuritis in Intracranial Disease are embraced in the chapter on Diseases of the Optic Nerve. Valuable additions are also noticed in Diseases of the Ocular Muscles. The editor's own views are furthermore introduced in the various sections throughout the work.

A critical examination at once shows the fidelity and thoroughness with which the editor has accomplished his part of the work, and he is eminently deserving the thanks of the profession. The illustrations throughout are good. On the whole, this edition can be recommended to all as a complete treatise on diseases of the eye, than which probably none better exists.

A TEXT-BOOK OF GENERAL PATHOLOGICAL ANATOMY AND PATHOGENESIS. By ERNST ZIEGLER, Professor of Pathological Anatomy in the University of Tübingen. Translated and edited for English students by Donald MacAlister, M.A., M.B., Member of the Royal College of Physicians; Medical Lecturer of St. John's College, Cambridge. New York: William Wood & Co., 56 and 58 Lafayette Place. 1883.

THIS volume, containing 355 pages of reading matter, with 117 illustrations, is a part of the work being written by Professor Ziegler, and constitutes the seventh of the series in Wood's Library for 1883. The established reputation of the author places the work at once in the catalogue of valuable contributions to recent medical literature. It exhibits strongly the personality of the writer, a feature worthy of special commendation. Professor Ziegler advocates doctrines which may not be readily accepted, but they are not unreasonable, and it should not be argued, because of the difference of opinion on certain technical points, that his conclusions are necessarily faulty. They are given concisely and independently, and, by reason of their possessing these characteristics, are additional material worthy of careful study and comparison. To facilitate such work the translator and editor has, in an acceptable manner, given in brackets the views entertained by many of the most eminent observers on the points where Ziegler has advanced new theories. The translation seems to have been done well, and the annotations make an important part of the book. As a whole, the volume is another excellent one in the series for 1883. The second part—on Special Pathological Anatomy—is in course of publication in Germany.

THE MEDICAL REGISTER OF NEW YORK, NEW JERSEY, AND CONNECTICUT, for the Year ending June 1, 1883. WILLIAM T. WHITE, M.D., Editor. New York: G. P. Putnam's Sons. 1883.

THIS annual volume presents its usual appearance, and is under its usual able editorial management. It contains the names of 5,969 physicians, distributed in the States of New York, New Jersey, and Connecticut. The New York City list contains 1,661 names, forty more than last year.

For a long period this book has been accepted as an authoritative register of the regular profession of New

York, New Jersey, and Connecticut, and in order to maintain such a reputation the greatest care should be taken on the part of editor and co-laborers to make it accurate and impartial. We notice one or two omissions in this regard, which, it is to be hoped, are simply accidental; otherwise the work is everything it should be.

THE BACTERIA. By T. J. BURRILL, Ph.D., of Springfield, Ill.

THIS is the title of a pamphlet giving a complete but concise account of the nature, kinds, and effects of the different bacteria. It is the best monograph on the subject we have seen, and is highly creditable to American science.

MEDICAL ECONOMY DURING THE MIDDLE AGES: A Contribution to the History of European Morals, from the Time of the Roman Empire to the Close of the Fourteenth Century. By GEORGE F. FORT. New York: J. W. Bouton. London: B. Quaritch. 1883.

UNDER the above somewhat delusive title, the author has written a kind of history of medicine. It is called "Medical Economy," because it deals with medicine more especially in its relation to law and society. As the full title shows, the book covers more than the middle ages. It takes up medicine at the time of the Ptolemies, traces the growth of the Alexandrian and Roman schools, and subsequently the progress of medicine down to the fourteenth century. The book shows a vast deal of erudition and research, if one may judge by the numerous references. It is not written, however, in so coherent and attractive a manner as it might be. In fact Mr. Fort has a bad literary style. There is a great deal in it, however, that physicians will find curious and interesting. Typographically the book is an excellent specimen of English work.

THE SANITARY ENGINEER, Vol. VII. 4to, pp. 620. New York: Henry C. Meyer. 1883.

THE seventh volume of *The Sanitary Engineer* includes the twenty-six weekly issues from December 7, 1882, to May 31, 1883. Among the articles of permanent value may be mentioned "Letters to a Young Architect on Heating and Ventilation," by Dr. J. S. Billings, U.S.A.; "Steam Fitting and Steam Heating," by "Thermus" (a series—illustrated); "The Edison System of Wiring Buildings for the Electric Light" (illustrated); illustrated descriptions of the sanitary arrangements in the residences of Cornelius Vanderbilt, Esq., the Berkshire Apartment House, Home for Aged Females, and the Duncan Office Building; "The Steam Heating Companies in New York" (illustrated description of); full abstract, with illustrations, of the records in the McCloskey Patent Suit for Trap Ventilation; "The New York Water Supply," a series of articles on the suppression of waste of water, giving the experience of European cities in attempting to deal with this problem, the practice now in vogue there, and the situation in American cities—these articles will be found of great value to water works authorities and all who are interested in this question; a discussion of the various projects for increasing the water supply of New York, including the Croton Aqueduct scheme, appears in almost every number in this volume; "Atlantic Coast Resorts," a report by E. W. Bowditch, C.E., to the National Board of Health; "National Board of Health," Congressional Debates on the; "How the Plumbing Law is Enforced in New York," a description of the methods employed by the department; "Germs and Epidemics," by Dr. John S. Billings, U.S.A.; "Malaria" (a series), by George M. Sternberg, Surgeon U.S.A.; "Lead Burning," apparatus and process described; "Gas-Fitting in an Office Building," description of work in Mills Building; "American Practice in Warming Buildings by Steam," by the late Robert Briggs, M. Inst. C.E.; a paper read before the Institution.

There is also the current information of the operation of the food adulteration laws; record of rulings and prosecutions, and copies of laws. The weekly and monthly mortality table of the principal cities of the United States, together with a large amount of home and foreign health notes.

Correspondence.

COPPER AND CHOLERA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The occurrence of a case of cholera in London makes the three thousand miles of Atlantic Ocean between it and New York seem but a slight barrier. The apprehension already felt since its appearance on the shores of the Mediterranean is at once increased. It is a scourge, according to the *Tribune*, which "has defied the medical science of the present century." It is true that the epitaph of many victims might read, "physicians' skill was vain;" nevertheless may it not be said that it has saved many others?

Incidentally the Paris correspondent of *THE RECORD* of July 7th has referred to a part of Dr. Burq's theory in regard to the use of copper in cholera, that of giving it internally. Slight, if any, mention is made of it in the treatment of cholera as set forth in text-books, encyclopædias, and general works of medicine, although it is now more than thirty years since Dr. Burq has advocated it and regarded it as a valuable, if not an unfailing remedy.¹

In his experiments with copper in 1848, at which time he made the discoveries which led to the introduction into medicine of the external and internal use of metals as therapeutical agents, he found that copper was efficacious in allaying spasms; from this, coupled with the fact that workers in that metal almost always experience an immunity from cholera, he obtained the idea of using it in the severe cramps of that disease in the epidemic of 1849. His treatment consisted in placing plaques or disks of copper over the stomach as well as the internal administration of the sulphate.²

Rostan, in his "*Leçons Clinique sur le Choléra*," says that the use of the copper armatures was almost always attended with success.³

The fact that the copper workers escaped cholera is recognized in Paris by *chefs* of that industry: scientists and *savants* of France, Italy, Sweden, and Russia. It was confirmed by the results of the investigations of the prefecture of the police after the epidemic of 1865-66, as well as by the reports of M. Levy in 1867, M. Verneuil, in 1869 and 1874.

Dr. Panchon says that an impregnation of the system with the dust of copper obtained by workers in it has insured an immunity in all the epidemics of cholera, a preservation not less certain than vaccination in small-pox.

It might be added, in passing, that artisans in these metals also escape typhoid fever. A society of bronze-workers, during a period of thirty-six years, lost no member from typhoid fever. In the epidemic of this disease in 1876, only two deaths occurred among thirty thousand workers in copper, and it was a noteworthy fact that these two had to do only with large pieces.

It has not been recorded, so far as I am aware, that insufflation of copper-dust has been practised as a prophylactic measure in cholera epidemics; but Dr. E. Mailhet,⁴ a physician in the East, having read Dr. Burq's articles on the use of copper in cholera, when an epidemic broke out near where he was stationed, caused belts of the metal to be worn over the abdomen as a preventive

¹ Des Origines de la Metallotherapie, *Gaz. des. Hôp.*, 1882, p. 522.

² *Ibid.*, November, 1849.

³ *Ibid.*, Avril, 1880, p. 299. *Compt. Rend. d. Soc. Biol.*, 1879.

⁴ E. Mailhet: Choléra et Emploi du Cuivre: *Gaz. des Hôp.*, 1877.

measure. Six hundred persons were thus fortified. In an adult population of three thousand, one hundred were attacked with cholera and cholérine, but not one of those who wore the copper plaques were among the number, nor was any old woman who wore a small *scapulaire* of copper of the dimensions of half a franc.

These facts and results are certainly very suggestive, and deserve more consideration than they have received, judging from the little that has been said or written about them. Perchance the very simplicity of the measure has caused it to be overlooked or set aside as contrasting too markedly with the gravity of the disease.

GRACE PECKHAM, M.D.

5 LIVINGSTON PLACE, N. Y.

THE ELIZABETHAN DRAMATISTS AND LATER POETS ON THE PRINCIPLES AND PRACTICE OF PHYSIC.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It occurred to the writer that a brief compilation of excerpts bearing (or seeming to bear) on medical practice, from the works of the dramatic contemporaries of the great sovereign poet (those lesser lights around the central sun), also those of some of the poets of the seventeenth and eighteenth centuries, might be worthy the attention of members of our profession. If it show naught else, it will serve to make manifest how important an element and factor physic has ever been both in life and literature; being, as it were, woven and immeshed in the warp and woof of this our mortal life. Hence an *historic* and *literary*, in addition to the intrinsic and scientific, interest attaches to medical practice. Furthermore, unquestionably it is good for us as practitioners occasionally to step outside the exclusive boundaries of the strictly scientific aspects of physic, and to regard our art from other and different stand-points. For medicine (in its largest and most catholic sense) is so interwoven with human weal and woe, that it is as impossible as it would be undesirable to separate it from the great general currents of life and thought.

First comes great MARLOW with his "mighty line:"

1. INSOMNIA.

"So that for want of sleep and sustenance
My mind's distempered."

—MARLOW: *Edward II.*

2. INSANITY.

— "yet they do act
Such antic and such pretty lunacies
That spite of sorrow they will make you smile."

—DEKKER.

3. PYÆMIA.

— "conveys infection
Dangerous to the heart."

—JOHN FLETCHER: *Faithful Shepherdess*.

4. SENILITY AND LUNACY.

"Grows lunatic and childish for his son."

—THOMAS KID.

5. ARTERIAL AND VENAL CIRCULATION.

"My blood flew out and back again as fast . . ."

—BEAUMONT AND FLETCHER: *Philaster*.

6. DISSECTION ROOMS.

"For they are able to putrify it, to infect a whole region."

—MIDDLETON: *The Witch*.

7. HYGIENE.

"I'll walk to get me an appetite; 'tis but a mile."

—MASSINGER.

8. SANGUINEOUS CIRCULATION.

"What an elasticity in her veins and arteries."

—SIR RICHARD STEELE: *The Constant Couple*.

9. ADIPOSITY.

—"Exercise will keep me from being pursy."

—MASSINGER: *A New Way to Pay*.

10. SURGERY.

"Why, sir, there are above five hundred surgeons in town."

—GEORGE FARQUHAR: *The Constant Couple*.

11. PHYSIC.

—"you have broke the *patent medicine* chest, that was to keep them all alive."—MORTON: *Speed the Plough*.

(N.B.—This excerpt is interesting as being an early reference to *patent medicines*!)

12. LACHESIS.

"I eat snakes, my lord, I eat snakes."

—DEKKER: *The Honest W.*

(N.B.—The homœopaths have a remedy they call *lachesis*, supposed to be made from serpent-poison; and in the back towns of Italy *viper-broth* is still occasionally used.)

13. CEPHALOTRIPSY.

—"and offer luke-warm blood of new-born babes."

—MARLOW: *Dr. Faustus*.

14. BOTANIC PHYSIC.

"What herbs hast thou?"—MIDDLETON: *The Witch*.

15. PREGNANCY.

—"her midwives, her nurses, her longings every hour."

—BEN JONSON: *The Alchemist*.

16. AGUE-CAKE AND SPLENOTOMY.

—"your spleen; out with it,
I know you're like to burst."

—GEO. FARQUHAR: *The Constant Couple*.

17. VINUM OPII.

—"and the opiate that brings me sleep."

—TH. MORTON: *Speed the Plough*.

18. CONSTIPATION.

"When will your costiveness have done, good madam?"

—CARTWRIGHT: *The Ordinary*.

19. QUACKERY.

JOHN CASE, a quack of James II.'s time, like Mr. Wegg, occasionally dropped into poetry. He put the following distich over his door, by means of which, it is said, he made more money than ever Dryden did by all his poetry:

"Within this place
Lives Doctor Case."

20. LACTATION vs. "BOTTLE-BABIES."

"When thou shalt breed thy child, nurse it with thine own paps."

—MARLOW.

21. APOPLEXY.

"Flat on the ground and still as any stone,
A very corpse, save yielding forth a breath."

—THOMAS SACKVILLE (A.D. 1559).

22. GINSENG (*panax quinquefolium*).

"Here's *panax* too. My pan akes, I am sure, with kneeling down to cut 'em."—MIDDLETON: *The Witch*.

(N.B.—This drug, on which Dr. Piffard, of New York, lately prepared a valuable paper, is to-day, and has been for centuries, the Chinese panacea. It sells in Peking for its weight in gold.)

23. AMAUROSIS.

"O dark, dark, dark, amid the blaze of noon."

—MILTON: *Samson Agonistes*.

24. PREGNANCY.

"I have heard that great-bellied women do long for things that are rare and dainty."—MARLOW.

25. IODOFORM AND ASAÆTIDA.

—"your stench it is broke forth"—JONSON: *Alchemist*.

26. CINCHONA.

"And yet more medicinal is it than moly."—MILTON: *Comus*.

27. CARDIAC HYPERTROPHY.

—"Into the solid heart"—FLETCHER.

28. AUTOPSY.

(*Cadaver, log.*)

—"Yet send me back my heart and eyes."—JNO. DUNNE.

29. MAMMARY ABSCESS.

"But why that bleeding bosom?"—POPE.

30. LEUCORRHEA.

—"it was a weakness in me,
But incident to all our sex."

—MILTON: *Samson Agonistes*.

31. SYPHILIS.

"He'll feel the weight of 't many a day."—COWLEY.

32. LUXATION OF INFERIOR MAXILLA.

—"with gaping mouth."—SPENSER.

33. LOCOMOTOR ATAXY.

"Obliquely waddling to the mark in view."—POPE: *The Dunciad*.

34. MORPHIA SULPHATE.

—"the virtue of this magic dust."—MILTON: *Comus*.

35. OPHTHALMIA TARSII.

"Have you your ointments?"—MIDDLETON: *The Witch*.

36. ANASARCA.

"I fondly thought he could not live a year,
But now his dropsy's better."

—INCHBALD: *Every One Has His Fault*.

37. ACONITE.

—"among the rest a small unsightly root
But of divine effect."—MILTON.

38. BRONCHITIS.

—"and his cough,
Not the least chance for that to take him off."—INCHBALD.

39. PODAGRA.

"Sir Tristram Testy worn with age and gout.
Within all spleen, and flannel all without."—*Ibid.*

40. BEASTLY REMEDIES.

"Learn from the beasts the physic of the field."—POPE.

F. BRADNACK, M.D.

211 EAST EIGHTY-SIXTH STREET, N. Y.

TAYLOR'S METHOD OF EXTRACTING CATARACT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: There has been much said and written of late in reference to a new method of extraction of cataract, in which the incision is made wholly within the cornea, and without excision of the iris; and there seems to be an impression that Galezowski is the originator of this method. As the meed should belong to him who has really earned it, and especially for such a valuable contribution to ophthalmic surgery, I draw your attention to the fact that Dr. Charles Bell Taylor, of Nottingham, England, is the real originator of this operation.

In the *London Medical Times and Gazette* of February 12, 1876, it states that at a meeting of the Clinical Society on January 28th of that year, under the head of "A New Operation for Cataract," "Dr. Charles Bell Taylor, of Nottingham, introduced patients who had undergone extraction of cataract by a method which he had adopted in favorable cases since 1865. The lens, he said, was removed through a small flap, the base of which occupied a position about midway between the horizontal diameter of the cornea and the corneo-sclerotic junction. The wound healed readily. There was no subsequent astigmatism, and as there was no trace of the operation a few weeks after its performance, the lower section, on account of its greater convenience, was selected. The patients introduced were said to be average examples, had central and movable pupils, and all trace of the operation was so completely effaced that it was impossible to say whether the flap had been made upward or downward, or that the patient had undergone an operation.

"Dr. Taylor stated that the highest amount of visual acuity obtainable after extraction was secured in this way, some of the patients declaring that they saw as well as ever in their lives before."

Further on in the proceedings of the society, Dr. Taylor took occasion to specify the kind of cases in which the operation was performed without an iridectomy: "Where the pupil dilated well under the influence of atropia there should be no iridectomy. When the pupil did not dilate well with atropia, and where there were adhesions, or when it (the iris) became wounded during the removal of the lens there should be an iridectomy."

Dr. Macnamara in discussing the cases of Dr. Taylor, said: "the results of the operation were splendid." He thought that excision of the iris was generally uncalled for in the extraction of cataract, certainly in those cases where atropine dilated the pupil.

Dr. Watson congratulated Dr. Taylor upon the results in his cases, and said he "could detect no trace of the operation upon the cornea except by means of a magnifying glass."

Dr. B. Carter had seen so many of Dr. Bell Taylor's beautiful results that he "could quite endorse Mr. Watson's last statement." At the same time he thought that removal of the iris left the eye in a better condition for healing. He discouraged the operation without iridectomy, and claimed "that the optical results were never below the standard obtained in the cases without iridectomy."

In my own practice I have followed the suggestions

of Dr. Taylor since reading the proceedings of the society in 1876, and have been gratified with the results.

One gentleman, seventy-seven years of age, who was operated on three years ago, writes me and says he sees as well as he did twenty years ago. Another gentleman wrote me of his wife, who was sixty-seven years of age when I operated on her eyes four years ago, and says that "she can see to read, and thread a fine needle." I have operated on as many as seventeen successive cases in the manner described by Dr. Bell Taylor without a single failure, and with the most gratifying results in every case.

I own that I owe my success in this line of practice to Dr. Taylor, and hope the honors may rest where they belong.

L. W. WRIGHT.

COLUMBUS, O., August 8, 1883.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 4, 1883, to August 11, 1883.

MAGRUDER, DAVID L., Lieutenant-Colonel and Surgeon. Leave of absence extended one month. S. O. 89, Military Division of the Missouri, August 4, 1883.

MCPARLIN, THOMAS A., Lieutenant-Colonel and Assistant Medical Purveyor. Relieved from duty in charge of the purveying depot in San Francisco, Cal., to take effect September 1, 1883, and will then proceed to New York City and relieve Assistant Medical Purveyor, Ebenezer Swift, of the charge of the purveying depot in that city. Assistant Medical Purveyor McParlin will transfer all funds and public property in his possession to Medical Storekeeper Henry Johnson, who, until further orders, will perform the duties of Acting Assistant Medical Purveyor, at the purveying depot in San Francisco. S. O. 183, par. 5, A. G. O., August 9, 1883.

FORWOOD, WILLIAM H., Major and Surgeon. To proceed to Fort Washakie, Wyoming, and Fort Ellis, Montana, on public business and return. S. O. 87, Military Division of the Missouri, August 2, 1883.

WOODWARD, JOSEPH J., Major and Surgeon. Leave of absence granted on account of sickness, by S. O. 34, extended six months. S. O. 179, A. G. O., August 4, 1883.

BANISTER, JOHN M., First Lieutenant and Assistant Surgeon. Relieved from duty in the Department of the Missouri, and assigned to duty in the Department of the East. S. O. 183, par. 5, A. G. O., August 9, 1883.

CARTER, WILLIAM F., First Lieutenant and Assistant Surgeon. Relieved from duty in the Department of Texas, and assigned to duty in the Department of the East. S. O. 183, par. 5, A. G. O., August 9, 1883.

KANE, JOHN J., First Lieutenant and Assistant Surgeon. Relieved from duty in the Department of the Missouri, and assigned to duty in the Department of the East. S. O. 183, par. 5, A. G. O., August 9, 1883.

BYRNE, CHARLES B., Captain and Assistant Surgeon. Relieved from duty at Fort Craig, N. M., and assigned to duty at Fort Lewis, Col. S. O. 161, par. 3, Department of the Missouri, August 6, 1883.

LAUDERDALE, JOHN V., Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect on or about the 15th instant. S. O. 90, par. 2, Department of the Missouri, August 6, 1883.

OWEN, W. O., Jr., First Lieutenant and Assistant Surgeon. To proceed from Vancouver Barracks to Fort Walla Walla, W. T., and report to the commanding officer of the latter post for temporary duty. S. O. 101, Department of the Columbia, July 27, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending August 11, 1883.

GATEWOOD, J. D., Passed Assistant Surgeon. Orders to the Trenton revoked and ordered to the Kearsarge.

SCOTT, HORACE B., Assistant Surgeon. Detached from the Receiving Ship Franklin at Norfolk on the 30th inst., and ordered to the Trenton on September 1st.

AUSTIN, A. A., Passed Assistant Surgeon. Detached from the Richmond and waiting orders.

Medical Items.

CONTAGIOUS DISEASES.—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 14, 1883:

THE QUESTION OF THE LEGAL RIGHTS CONFERRED BY THE POSSESSION OF MEDICAL DIPLOMAS.—Dr. Rauch, Secretary of the Illinois State Board of Health, says, in his last quarterly report: "This occasion may be taken to offer a word or two of comment upon the impression which obtains in certain minds concerning the sacred rights of 'legally-chartered colleges,' and the virtues which inhere in anything called a 'diploma,' no matter whence it emanates. The latest form in which this has found expression is as follows: 'If a physician be such by virtue of the laws of the State of New York has the State of Illinois power to disqualify him for practise? If she should attempt this, there can be but little question that an issue will be taken in some case for final presentation at the bar of the Supreme Court of the United States.' The question in the above is based upon an erroneous impression as to the rights, privileges, and immunities which medical colleges can confer with their diplomas. The assertion which follows, and which seems intended to forestall answer to the question, is based upon want of familiarity with important facts connected with the medical profession in Illinois. To correct this latter, it is only necessary to point out that in the enforcement of the Medical Practice Act in this State, hundreds of physicians, who were such by virtue of the laws of New York or of other States, have been disqualified from practice in this State during the past six years; and that scarcely a day—never a week—passes when one or more such physicians are not so disqualified and leave the State (*vide* the reports and records of the State Board of Health, *passim*). The error as to the rights conferred by the diploma of a college chartered in accordance with the laws of any given State—which is, probably, what is meant by 'a physician by virtue of the laws,' etc.—has been corrected more than once by the courts, and in the publications of this Board. While it is true that every man has a natural right to follow out the bent of his inclination, and to be a clergyman, a lawyer, a doctor, a scavenger, a peddler, an auctioneer, just as he may choose, it is not true that a man can practice any of these professions or occupations except he does it upon such terms as the law imposes; and the law can

impose just such terms upon any one of these professions or employments as the legislators in their discretion deem best for the interest of the community. A legally-chartered medical institution in New York, or in Wisconsin, or in Missouri, or Massachusetts, may graduate its 'students' and endow them with diplomas conferring upon them the rights and privileges of doctors in medicine—subject to the laws, not only of the State but of the community in which they practise. But when such 'physicians' enter Illinois to practise, they must conform to the Illinois law. The right to practise medicine is not a constitutional right, nor a right inherent in the law of nature, nor an absolute right conferred by a college, whether specially chartered or otherwise. It is a statutory right, subject to the control of the Legislature; and the Legislature of this State has prescribed the terms and conditions upon which it may be exercised in this State. Among these terms and conditions is one to the effect that the practitioner, if a graduate, shall present the diploma of a college in 'good standing'; and it devolves upon this Board, by the terms of the law, to determine what colleges are, and what are not, in 'good standing.' Only the graduates of such—with exceptions not pertinent for consideration in this connection—may practise medicine in Illinois, no matter what rights the laws of another State may confer in that State. It has seemed necessary to say this at the present time—without any reference at all to Springer of Hardin, and the President of the St. Louis Eclectic—for the reason, among others, that it is a matter of importance to the student of medicine, intending to practise in this State, that he pursue his studies at colleges which comply with the requirements of this Board."

THAT JUDICIOUS COUNCIL.—In referring to the clause which the Judicial Council of the American Medical Association had inserted on the slip which delegates were obliged to sign at the late meeting, and which was but a covenanting anew with the Code of Ethics, the *Philadelphia Medical Times* says: "We cannot, however, close without a word of praise for the dexterity which was shown in so strangling all ethical rebels that none of them succeeded in crossing the sacred Æsculapian threshold, and the shades of Hippocrates suffered no dishonor or distress over unseemly bickerings and disputings." The *Canada Lancet* ventures to predict that "this attempt at coercion will be followed by a reaction, which will have the directly opposite effect of what was intended."

LEMON-JUICE AND OYSTERS.—Many popular usages in ordinary life have been adopted either by instinct or from empirical notions, and thus it is a common practice to use lemon-juice with raw oysters. It appears, however, from the researches of M. Certes, a distinguished microscopist and biologist, that this practice is not only a matter of taste, but that it has its utility, as lemon-juice has the property of destroying the animalcules which infest the stomach of oysters. The moral to be drawn from this is that oysters must be cooked, or, if eaten raw, should be accompanied by lemon-juice to avoid the possible evil consequences of parasiticism.—*Lancet*.

THE FUNCTIONAL INDEPENDENCE OF EACH CEREBRAL HEMISPHERE has been demonstrated by Dumontpalier in the following experiments: An hysterical epileptic woman was hypnotised by pressure upon the vertex. She was told to take up the knitting which was laying by her side. She took it with both hands and commenced knitting. A pressure upon the left parietal bone arrests the motion of the right hand, while the left continues to work. The like effect is produced on the left hand, when the right parietal is pressed upon. Pressure upon the crown of the head causes her to awake. Consequently central pressure causes equal reflex action upon both hemispheres, while lateral pressure affects only one hemisphere, the opposite of the pressure. He provoked

illusions, hallucinations unilateral or bilateral. Another patient is hypnotized by a look. He places the tips of her finger upon her lips, and stays her arm as if about to throw a kiss. She maintains that position with a smiling expression of the left side of her face. At the same time he brings her right arm into the position, as if wanting to repel some unpleasant object. She retains this attitude, the right side of her face assumes the expression of horror, while the left side smiles. The firm angered features of a commander are seen on the right side, those of gentleness and benevolence on the left side. In this experiment the muscular action of each side has excited in the contralateral hemisphere a sentiment or an image which manifested itself in the same side of the face.

THE CODE OF ETHICS.—Referring to the pledge exacted of members who presented themselves for registration as members of the American Medical Association, the *Peoria Medical Monthly* says: "The whole thing was an insult to the members of the Association, especially to those who had previously attended. It looked very much like applying the gag to keep the mouths of any opponents to the Code closed. It certainly gained no friends for the Code party, and really alienated many who were not previously opposed to it."

PROSTITUTION IN FRANCE.—In a recent work by M. Armand Després, of the Paris Faculty, devoted principally to statistics, and written in opposition to the recognition and licensing of the social evil by the State, the following figures are given (*Medical and Surgical Reporter*): There are in France 15,057 registered prostitutes, 7,859 belonging to maisons de tolérance, which number 1,328; 7,198 prostitutes are what is termed en carte—they live in their own rooms and appear at certain stated times (once monthly) for examination. Besides this prostitution recognized by the law, there is another, the individuals exercising it escaping as best they can the attention of the police. The number of free prostitutes is thought to be about 41,000. M. Després asserts that where prostitution is regulated by the State, and the danger from infection thus obviated, marriage is thought of later in life, and increase of population reduced to a minimum.

STATISTICS OF CONSUMPTION.—Dr. Playter, of Toronto, has gathered facts in regard to consumptives from 250 doctors. Their replies showed that the average age of patients was twenty-seven; 46 per cent. were males, 54 per cent. females, and 28 per cent. were married. The average size of the chest was 31½ inches; the chest of persons of the same average height, 5 feet 5½ inches, would usually average 37 inches. About 55 per cent. had light hair and eyes, two thirds did indoor work, had slept in small rooms, and wore no flannels. Only 46 per cent. had consumptive ancestors, and a majority were of nervous temperament.

THE PREDICTIONS OF GUITEAU.—The following curious paragraph, which is decidedly sensational and but partly true, is being circulated by English papers: "It is well known that Guiteau, the assassin of President Garfield, when upon the point of being condemned, made a prediction of sundry recompenses which would fall upon those who had contributed to his condemnation. Struck by a powerful malediction, its effects would promptly overtake them. That prophecy, says our correspondent, is being accomplished with startling rapidity. The wife of the attorney of the Corkhill district, who displayed so much ardor in the pursuit of Guiteau, died immediately after his condemnation. So died Surgeon-General Barnes, whose deposition was most hostile to Guiteau. Dr. Noble Young is also dead. Porter, the judge, whose 'charge' was so violently pronounced against the criminal, is in shattered health and incapable of duty. The marshal Henry, the bailiff Stahl, the detective McElfresh, Perry Corson, the guard, and James Leonard, the prison coachman, are destitute. The Rev. Mr.

Hicks is pursued by defamation. Dr. Grevy has been killed in an asylum for the insane. Dr. McDonald is troubled on account of his administration of Ward's Island, and is the subject of Government inquiry. The sergeant, Mason, has been for a long time in prison, while his wife and a lawyer are fighting over some thousands of dollars subscribed by the enemies of Guiteau. The wife of one of the jurymen (Hobb) has died, and the jurymen Mike Scheban has been struck by madness. Thus ends for the present this 'tale of woe.'

MEDICINE AT PRAGUE.—Dr. Councilman writes to the *Maryland Medical Journal*: "At present there is a great rivalry and a degree of hatred, difficult to overestimate, between the Germans and the Bohemians. It has finally reached such a pitch that the latter refuse to have anything to do with the Germans, refuse to learn their language, and this fall they will have a new university, in which all the lectures will be given in Bohemian. As the Bohemians have never been very celebrated for their scientific or literary acquirements, and as no one would learn their language, even for the sake of being professor, the number from whom their professors must be chosen is necessarily a limited one. Stricker's assistant in Vienna, Spina, who lately has written an article on the poor, much maligned tubercle bacillus, an article which almost rivals the classic production of Schmidt on the same subject, has been called to the chair of General Pathology, and the other chairs will also soon be filled."

SINGULAR DEATH-RATE IN PENITENTIARIES.—The death-rate in the principal penitentiaries or prisons in the country furnishes a notable feature in the report of Dr. Gill, of the Illinois Prison, the variations in the different institutions being almost incredible. Thus, among New York prisons, while at Sing Sing the yearly deaths from one thousand inmates number, as stated, a trifle less than seven, at Auburn it is given as twelve, and at Clinton over twenty. The lowest rate named is three in Wisconsin, and the highest, seventy-seven, in Mississippi. The practice of "letting" convicts for work on mines and railroads is declared to cause fearful death-rates in several Southern States, but, on the other hand, the New Hampshire figure is forty-eight. The rate in Massachusetts is given as fifteen, in Maine the same, in Vermont twenty-five, and in Connecticut fifteen. Pennsylvania has six in the western and fourteen in the eastern district.

THE HUMBUG OF CONSULTATIONS.—A certain well-known physician, who enjoys the distinction conferred by a titled name, was recently called into the country for consultation with the personal attendant on a noble lord. After a stay proportioned to the gravity of the case and the social importance of the illustrious patient, the eminent physician departed for the station, mutual satisfaction having resulted from the visit. While pacing the platform, however, the centre, we may be sure, of concentrated village admiration and awe, the great light of modern medicine was suddenly confronted by a breathless but much belivered minion of the sick nobleman, who, with many apologies uttered in his master's behalf, begged the M.D. Bart. to supplement the directions he had already given with information respecting the merits of grapes as an article of diet for the invalid. The request was received with a gracious bow given in approving recognition of the thoughtful nature of the application, and then ensued a spectacle of sublime significance. For about a minute the eminent one slowly paced in pondering thoughtfulness, and then gave forth, as a result of full consideration of an important, nay, vital, problem: "Tell his lordship that he may eat grapes, but *white ones only*; be sure and impress this upon him—that he must on no account touch any others; white ones, and no more than six per day." The fast-coming express just then approached the station, and while the great one sped away to the London anxiously awaiting him, the awe-struck servant returned to tell the tale, how the vast

intellect of the mighty consultant could even discriminate between the harmless influence of white grapes and the poisonous properties of colored ones. This little narrative was communicated to me by "one who knows" on Sunday last; and it has seemed to be worth repeating as an example of the refinement to which the humbug of consultation may extend. It is palpably clear that any such exhibition as that described above could ever be indulged in with one intent only, and that the magnification of the exhibitor's claims to knowledge.—*London Medical News*.

ANOTHER CASE OF THOMSEN'S DISEASE.—Dr. Schönfeld, assistant-surgeon in the German army, has reported a case of this disease, concerning which we wrote a short time ago. Hitherto the number of cases reported has been very few, and most of them were confined to one family. Schönfeld's case was that of a young recruit who was bitten in the leg by a dog, very severely, six years before. The fright and injury were thought to have been the active cause of the disease.

CONCERNING PARASITES IN THE LUNGS.—Dr. R. Van Santvoord, of New York, writes: "Your correspondent, Dr. Mann, of Portland, Oregon, will find in the *London Lancet*, of March 31, 1883, page 532, an article by Dr. Maurer, of Amoy, China, on "Endemic Hæmoptisis," which may be of service to him in connection with his reported cases of "Parasites in the Lungs." The "Endemic Hæmoptisis" of Dr. Maurer is also of parasitic origin, but the parasites in his cases were represented in the sputum by ova only, the adults being found post-mortem in the air-passages, and differing apparently from those coughed up by Dr. Mann's patient."

MOIST HANDS.—Mr. H. A. Smith writes, in the *British Medical Journal*: Moisture of the hands (local hyperidrosis) is a purely functional disorder of the skin, due to disturbances of the nervous system. Stout women, generally servant girls, suffer from it, although the fair votaries of the ball-room and members of good society, together with those of lithe and nervous habit, occasionally come under notice. It may or may not be attended with pain and inflammation, dysidrosis or fetor-smidrosis, or, more rarely, pigment-chromidrosis. As a rule, the axilla and feet sympathize more or less. As the condition appears to be due partly to abnormal vascular conditions, but mostly to irritability or undue stimulation of the vaso-motor nerves, probably of central origin, the following lotion will be found exceedingly useful:

R. Liq. plumbi subacetatis. ʒ iij.
Sp. vini methylati. ʒ j.
Aqua rosæ. ad ʒ x.
Fiat lotio.

The lotion to dry on, and the hands subsequently to be dusted three times daily with powder composed of equal parts of calamine and starch-powders. The patient should wash the hands always in cold water, and well dry them, and should avoid malt and all fermented liquors, pickles, spices, tea, and coffee (taking cocoa), and be sparing in the use of sugar. The lotion failing, she should wash the hands thrice daily with carbolie acid soap in soft water, in which half a dram of extract of belladonna has been previously dissolved, and take a pill containing valerianate of zinc, two grains; quinine, one and one-half grain; and extract of belladonna, one-fourth grain, with conf. rose q. s., t. d. s. A mixture (if any tingling or burning in the fingers) containing bromide of potassium, digitalis, and a vegetable tonic, will complete the treatment. The belladonna, besides causing vaso-motor paralysis, contracts the unstripped muscular fibres surrounding the arterioles going to supply the sweat-gland, and carbolie acid has a benumbing effect on the nervous filaments supplying these and the papillæ of the skin proper.

A NEW HOSPITAL AT CHICAGO is to be built by the Rush Medical College.

THE POSITION OF THE AMERICAN MEDICAL ASSOCIATION.—We cannot refrain from penning our dissent to the decision of the American Medical Association refusing to take any steps looking toward a revision of the existing Code of Ethics of that body. The petition of the St. Louis Medical Society was eminently proper, and we believe should have been adopted; but instead of being allowed discussion, it was promptly tabled, although by not a very heavy majority. We believe we voice the sentiments of a full majority of the reputable, regular profession in this country to-day, in saying that the Code of Ethics can and ought to be so revised as to be made a living law instead of the dead letter it now is. Many who talk the loudest in its favor are the most flagrant offenders against its spirit; such will always vote against a revision, for in its stilted language and antiquated and sometimes ambiguous construction they can always be able to escape the penalty of its violation, and to themselves, at least, excuse their wrong doing.—*Peoria Medical Monthly*.

THE RECENT MEETING OF THE AMERICAN MEDICAL ASSOCIATION at Cleveland, while generally profitable to those in attendance, was not without its disagreeable features, and it is with the hope that they may be avoided in the future that we call attention to some of them now. It certainly is not expecting too much of the Committee of Arrangements that they should see to it that delegates are at least provided with suitable lodgings. This was not done at Cleveland, so we are informed, but many, left to shift for themselves, experienced great difficulty in finding accommodations, and then, in the matter of registration, delegates were kept waiting, closely packed, for hours for an opportunity to sign their names, when provision should have been made by which it could have been done in much less time. There was difficulty also in obtaining information as to the departure of trains and in securing tickets, and the situation was truthfully described by one agent, who said, "I have had experience with a good many conventions, but I have never yet seen one where there has been such poor management as at this." Now the fault lies entirely with the Committee of Arrangements. This committee, we are told, was not at all harmonious in its workings, but was divided by differences of opinion which, in one instance, led to a personal encounter between two of its members, and so, from lack of harmony among themselves, the association was made to suffer. It seems that the committee, either willingly or unwillingly, surrendered to the *ipse dixit* of one of their number, and that he, swelled out of all proportion with a false estimate of his own wisdom and importance, undertook the management of everything, and, as might be expected, many things were left undone which would have added to the comfort and pleasure of the delegates.—*Weekly Medical Review*.

PLASTER-OF-PARIS PESSARIES.—Dr. B. F. Dawson states that he has made use of plaster-of-Paris, moulded within the vagina, with the most decided success, in two cases of displacement of the uterus (*New York Medical Journal*). The first case was that of a woman suffering from anteversion and a very aggravated prolapse of the left ovary. She was placed in the knee-chest posture, and pledgets of absorbent cotton, each with a string attached, soaked in a mixture of plaster-of-Paris and water of about the consistence of gum, and partially squeezed out, were placed in the posterior fornix of the vagina and around the vaginal portion of the cervix, and held in position. The vagina was then cleaned out, in a few moments the cast had hardened, and the patient went away with instructions to withdraw the instrument should it cause pain. When she came back at the end of three days she said she had experienced great relief. On removing the plaster pessary, the mucous membrane with which it had come in contact, instead of being irritated, as one might have expected, was found to have been benefited by its presence; it was firmer and less irritable

than before, and the prolapsed ovary had evidently been sustained. The second case was one of retroflexion, in which the pessary acted not only as a harmless agent, but seemed to give all the uterine support desired. The instruments were removed, placed in fire to burn out the cotton, and dipped into wax or paraffin for the purpose of making them impervious to the secretions and to render them more durable. This method of supporting the uterus commended itself for the facility with which it could be applied, for cheapness and accuracy of adaptation.

ST. LOUIS MEDICAL SOCIETY AND THE CODE.—On June 23, 1883, Dr. Atwood introduced the following, which was adopted by the St. Louis Medical Society, after some considerable discussion:

"Whereas, At the recent session of the American Medical Association, a preamble and resolution were offered for the consideration of said Association, purporting to represent the sense of the St. Louis Medical Society upon the propriety of preparing a new code of ethics, or altering and changing the existing code in accordance with the present relations of the profession, and

"Whereas, In said preamble the assertion is made that 'the Code has accomplished all it was designed it should, but at present many of its features are obsolete and not adapted to our wants. The necessity of an early revision is very apparent, is loudly called for in all parts of our land, and cannot be repressed much longer. . . . The time has come when the loud and very soon universal call will have to be heeded;' and

"Whereas, The St. Louis Medical Society did not instruct, 'That the Committee be authorized to prepare a code of ethics which in their view will meet the wishes of the profession, and submit the same to the meeting of 1884;' therefore,

"Resolved, That the St. Louis Medical Society distinctly repudiates the statements contained in said preamble, and again expresses its fealty to the existing code of ethics as a time-honored and most suitable fundamental law of the profession, and specially deprecates any action calculated to reflect upon its loyalty to those principles which have heretofore secured immunity from the machinations of schismatics within or enemies without.—A. H. OHMANN-DUMESNIL, M.D., Rec. Sec."

CONCERNING THE TWO BUSHELS OF TONSILS AND OTHER MATTERS.—Dr. J. S. Thompson, of Indianapolis, Ind., writes: "In your journal, dated July 28th, Dr. W. N. Williams of this city indulges in some facetious and would-be learned remarks at my expense, and quotes 'Ray's Practical Arithmetic' to show how many tonsils it takes to make a bushel. It will be remembered that in the discussion of Dr. Jarvis's paper on 'Tonsillotomy without Hemorrhage,' I remarked that I believed that I had removed two bushels of tonsils and no hemorrhage followed, and that I considered the instrument of no use whatever except in cases of purpura hemorrhagica, or similar rare ones. Did any one present suppose for one moment that I had measured them? Had I been the essayist, of course I should have been more exact; but it was an off-hand remark, intended simply to show that in a great number of cases, in a twenty-three years' practice, no case called for any other instrument than a chisel-shaped guillotine, the inventor and maker of which have long since been in their graves. Now, let me say a few words concerning new instruments and modifications of old ones. Is it not natural that when one invents one of these, he very soon finds more cases on which to use it than do others? Look, for instance, at the multiplication of ophthalmoscopes during the last twelve years! Why, one cannot go to London or other cities without finding inventors' names given to them that one never even heard of before. And so it is in modifications of operations, some one's name must constantly be associated with this or that incision or mode of procedure, when its importance is insignificant beyond measure. For my part, I expect to go on excising 'scirrhus' and other forms of tonsils to

the end of my days without the slightest hesitation whatever; and I have not the least doubt that when the reports are all in it will be found that as many deaths from hemorrhage follow the extraction of a tooth as the excision of a tonsil."

HOW TO SLEEP ON A TRAIN.—Dr. Henry R. Stout of Jacksonville, Fla., writes: "In THE MEDICAL RECORD for August 4th, in the article, 'How to Sleep on a Railroad Train,' is it not a mistake to place the person with the feet toward the engine? I have tried both ways, and have found, and have advised others with equal success, that to sleep with the head toward the engine would insure sleep. The rapid forward movement of the train forces the blood to the extremity furthest from the engine. It is possible that this position causes a more rapid return of blood to the heart, but it is hardly reasonable, I think, that it would cause a hyperæmic condition of the brain."

A USEFUL SUGGESTION REGARDING CATHETERS.—Dr. Hüpeden calls attention to the danger of infection attending the use of catheters as at present constructed. The defective and dangerous portion of the instrument is the blind end beyond the eyes. The most careful cleansing may fail to destroy or remove all infectious matter from this part, and thus some disease may be communicated to the next patient upon whom the instrument is passed. To obviate any such risk it is only necessary to fill up with some solid material this blind extremity.—*Centralblatt für Chirurgie*, July 7, 1883.

THE PREVENTION OF BED-SORES IN NERVOUS DISEASES.—Dr. Thomas Browne, of the Royal Navy Hospital, Great Yarmouth, asserts that bed-sores can be prevented even in the worst forms of general paralysis. Dr. Browne offers no specific, but states that very careful nursing, frequent washing, change of clothes, the use of pads, water-beds, and special attention to diet are the measures to be employed. Bed-sores, he says, no longer occur in the Naval Hospital at Yarmouth.—*Nashville Med. Journ.*, June, 1883.

CONCERNING THE INOCULATION OF LYMPHATICS AND BLOOD CAPILLARIES.—Dr. Theobald Smith, of the Anatomical Laboratory of Cornell University of New York, writes: "In THE MEDICAL RECORD of June 16, 1883, an abstract is given of a communication to the Académie des Sciences of Paris, in which Dr. Guérin, supported by experimental evidence, maintains the inoculation of lymphatic and blood capillaries. The abstract is prefaced by the remark that Mascagni and Sappey also hold this view. Lately my attention was called to the *Comptes Rendus* of June 11, 1883, which includes a memoir by Sappey on this same subject, in which he, however, gives up his former position. A unique method of demonstrating and studying both the lymph and the blood channels in the same microscopic field—the latter fading away as the former come into view—led him to abandon the theory of inoculation. He says: 'Sustained by these new and precise facts, and no longer by simple induction, I conclude that there is no room for admitting this communication; the lymphatic vessels at their origin are everywhere hermetically closed.' Curiously enough, the prominent English journal of science, *Nature*, for June 28th, p. 215, incorrectly reports Sappey as having demonstrated by actual observation 'the intimate union of the radicles with the blood-vessels which had long been assumed on general grounds.'"

CARRYING THE CLINICAL THERMOMETER IN THE PANTALOONS POCKET.—Dr. D. S. Clark, of Rockford, Ill., writes: "The most convenient way to guard a clinical thermometer against accident that I have ever tried or heard of is simply to carry it in the pantaloons pocket, just as a knife is carried. I usually devote the left-hand pocket to this sole purpose. Let any physician try this plan and he will prefer it to every other. Now will physicians inform us as to the best method of keeping hypodermic syringes in working order?"

ROUND SHOULDERS, OR ANTERO-POSTERIOR CURVATURE OF THE SPINE.

BY CHAS. F. STILLMAN, M.S., M.D.,
NEW YORK.

"ROUND shoulders" is one of the most prevalent deformities, and yet very little attention is paid by surgeons to its treatment, although it is amenable to curative measures with as little discomfort as any other prominent deformity.

An inquiry into its anatomical and physiological characteristics affords a clue to the treatment, that being the portion of the subject which more directly concerns us in this paper.

The spine, viewing it from the side, is a column composed of twenty-four segments, upon which rests the head, and to this column in its dorsal region is also attached the thorax, and secondarily the upper extremities. The normal line of the spine is a compound curve, and it is retained in this shape by muscles disposed along its course, acting as do the stays to a mast, and opposing the effect of the weight of the head as a constant gravital force to increase the curves. When the normal degree of tonicity does not exist in these muscles, this increase in the curves is found and is further exaggerated in the region of the neck and shoulders by the tendency of the upper extremities and thorax forward, and by this forward tendency we obtain the contracted chest, the separated and protruded shoulder-blades, and the bent and stooping shoulders, all characteristic of the deformity in this region.

But as the line of direction must be maintained, when the head drops forward the lower part of the trunk also projects itself, giving rise to the appearance of flat nates, and causing it to appear as if the dorsal region projected very much backward beyond the normal line, as in Fig. 1.

The most common cause to which this deformity can be ascribed is muscular weakness, the inability of the back to recover the erect position after it has been relaxed. Relaxation of the back is the position of rest assumed by the trunk when the superincumbent weight is to be more fully borne upon the bodies of the vertebræ, and we then rely upon the ligamentous bands and attachments rather than muscular force to keep the body in this less fatiguing position; thus relieving the muscles from all necessity of the contraction which is required if the trunk be maintained erectly. In this position of rest the spine curves backward in the shape of a bow, from the sacrum to the head, the centre of the bow being in the middle dorsal region, the bodies of the vertebræ being crowded together throughout the whole extent of the spine (see Fig. 3), and the muscles not exerting their contractile force.

When the erect position is again assumed, the muscles should restore the normal spinal curves so that the head and upper portion of the trunk, with their appendages, become supported in the proper line of direction (Fig. 2).

But if the muscles lack tone or are fatigued, or the patient is indolent, the position of rest becomes habitual and we have the production of round shoulders as the result.

There are various degrees and forms of the deformity, dependent upon the age of the patient, the length of the spine, the regional muscular development, the sitting

habits, etc.; but these are sufficiently known to every practitioner not to require description here. The projection forward of the head and nates is not found to the same extent in every case, but seems to be compensatory—to permit the line of direction to be passed somewhat anteriorly to its normal position, in order that the body may be properly balanced while in the vertical position.

The *treatment* which concerns us most directly in this paper, may be considered under two heads—*mechanical* and *physical*.

The *mechanical treatment* consists in the use of properly devised apparatus for the restoration and retention of the normal curvature, and the mechanical problem this involves resolves itself into the reduction of the dorsal curve, since the cervical and lumbar are merely compensatory and will tend to regulate themselves.

We have already noted the fact that the exaggeration

Fig. 1.

Fig. 2.

of the curves of the spine produces undue pressure upon the bodies of the vertebræ in the dorsal region, and we must, therefore, turn our attention first to placing the spine in such position as will tend to separate the bodies and transfer pressure to the other surfaces of contact in the normal degree. To effect this we utilize the principle of gravity as an extending force. When the patient assumes the horizontal position upon a table so arranged as to have its padded edge under the shoulder-blades, as in Fig. 3, and then allows the head and upper extremity to gradually fall backward and downward, we have produced a series of curvatures exactly opposed to those exhibited by the round shoulders. You will observe, as the patient's head and shoulders descend, a gradual obliteration of the condition of round shoulders and a reproduction of the normal curves of the spine. The bodies of the vertebræ become freed from the crowding to which they have been subjected, and a physiological and true extension of the parts is effected—

the traction-force being the superincumbent weight, the cervical spine being placed in a state of extension by the weight of the head, and the dorsal spine in extension by the weight of the head, the neck, and the upper extremities. This combined weight, augmented by gravity, is simply tremendous as a traction or tractive force, and produces a true backward physiological *extension*. Do not confuse the words traction and extension, or substitute one for the other. Traction is the force which produces extension. The former is a cause, the latter an effect; the former is an active agent, the latter is a condition; or in other words, extension is a result of traction, and is the effect produced upon a joint by traction. The words are not synonymous, and should not be so employed. This principle of backward traction, by the weight of the upper extremities, is one which we have been utilizing lately, as a most satisfactory factor for the production of extension in Pott's disease, as we not only obtain as

Fig. 3.

much extension of the spine as we can by suspension (or traction by the lower extremity), but we obtain this in a backward direction, which enables us to apply leverage to obliterate the deformity to a more satisfactory extent than ever before, and with less discomfort to our patients.

We have now, by the use of the table, obtained great improvement in the condition of the deformity, and the question arises, how are we to retain this improvement when the vertical position is again assumed, as the posterior spinal muscles are impaired and have not sufficient power to hold the spine in its restored curves.

Although in slight or recent cases this can be accomplished by simple methods, yet a brace will often be a necessity in severe cases, and it is easy for us to construct one upon the principles which govern the reduction of the deformity.

We must strive to keep the patient in a state of hyper-erectness until the muscles have contracted and been exercised and invigorated sufficiently to render the use of a brace unnecessary, and if we glance at Fig. 3, and turn it in such manner that the supine figure will appear vertical, it will be seen that the figure is more erect than normal, *i.e.*, hyper-erect, and this position (of the dorsal, not the cervical spine) is necessary to the development of the impaired muscles as well as for its effects upon the spine itself.

Now, how to keep this position with a brace. It may be, to some extent, done with a strong back-frame, fashioned to the hyper-erect shape and put in position and secured while the patient lies upon the table in the extension position. This frame may be made of some metal which can be bent by the hands of the surgeon, but it must necessarily be made of such heavy material as to be too cumbersome for general use, for it must be sufficiently firm to withstand the tendencies of the deformity, as it matches strength of material against the tendency of the superincumbent weight to fall forward.

I must impress upon you the importance of having this frame fashioned to the hyper-erect shape, for if so made, and well secured to the body, the forward tendency of the body and the exaggeration of the dorsal curve are to some extent prevented by the strength of material and shape of the splint.

A second and much more satisfactory method of utilizing the backward traction in the formation of a brace is one constructed on my adjustable lever plan—the *fulcrum*, *F*, to be over the sacrum—the *resistance*, *R*, to be greatest just below the central region of the dorsal curve, and distributed all along the spine below this region, and the *power*, *P*, to be the forward tendencies of the upper extremities and head (Fig. 4), so that while the body is maintained erectly no force is exerted upon the spine at any point; but the least tendency to rounding the shoulders brings a power to bear exactly opposed to the power of the deformity, which increases automatically in proportion to the extent of the deformative force.

To construct a brace so as to bring the force to bear under these conditions we place a girth, provided with a sacral projection, about the hips (Fig. 5). From the upper edge of this hip-girth springs a pair of padded strips, one on each side of the median line, so as to avoid the spinous processes, and these strips extend upward to the middle dorsal region (Fig. 5). So far the brace is a substitute for the table, but to give it efficacy we must supply a frame for backward traction as a substitute for the backward force exerted by the weight of the upper extremities when the body is in the traction position (see

Fig. 4.

Fig. 5.

Fig. 3). To effect this, a light steel frame moulded to the shape of the back and extending from the sacrum to the cervical vertebrae is attached at its lower extremity to the hip-girth (as in Fig. 6) and there provided with a ratchet which admits of its being secured at any angle. The upper extremity of this frame is secured to the body by means of chest and shoulder-bands (Fig. 7), which buckle in front to a firm leather chest-plate, the use of which permits us to avoid the constriction and discomfort attending the use of bands passing around the chest without such intervention.

The action of the brace (Fig. 7) is, as you see, that of a lever, exerting its force in such a manner as to distribute its pressure along the spine and not at any one point; the dorsal centre being the point of greatest pressure, and the sacrum the least, the intermediate pressure being so graduated as to decrease from the dorsal centre to the sacrum. We thus see that direct pressure is provided to the greatest degree where it is needed most, *i.e.*, at the dorsal centre, and in the least degree where it is needed the least, over the sacrum; and there is thus no portion of the spine below the dorsal centre without direct support. This support and forward pressure is just in proportion to the backward angle

of the brace-frame and the forward tendencies of the deformity. In the beginning of the treatment this brace-frame may be secured at a considerable angle (Fig. 6), but as improvement ensues this may be lessened, until it lies flat upon the padded strips (Fig. 7) and becomes in its action a mere spinal support instead of a lever.

This brace makes an extremely effective and comfortable instrument, and can be made to exercise any desired degree of power on the deformity. But there are many cases which do not require so pronounced an instrument as this—cases in which the youth and inma-

Fig. 6.

Fig. 7.

turity of the patient have not as yet allowed the parts to become perpetuated in the abnormal curves to such an extent as to demand its use.

Such cases require merely a light, strong, compound spring, or pair of springs, which will act supplementary to the impaired muscles of the back, and if we can adapt this spring power to the form so that it will not be apparent to an observer that the patient is wearing an aid of this kind, so much more successful will we be in our practice. We must remember that this class of deformities is unattended by pain, and it is therefore desire for symmetry which brings them to you; so that if an unwieldy spring makes a protrusion along the course of the spine it would be an objection to treatment in the eyes of the patient. But it is possible, by incorporating into an ordinary well-fitting corset, a pair of compound springs, one on either side of the median line, to provide against the objection which attends the use of a single spring. The under springs are somewhat longer than the corset and are provided with pads at their extremities so as to allow sufficient grasp of surface to prevent the edges of the pads from digging into the flesh when the body is laced down to the springs (see Fig. 8). The upper springs extend to the neck and are connected to the chest-plate in front as in the lever brace. The only springs which we have used heretofore in the profession to combat round shoulders have been fashioned in an exaggeration of the normal curves of the spine—a shape which would tend to increase and intensify the abnormal curves which are symptomatic of the deformity.

Fig. 8.

To make round-shoulder springs effective, however, the curves of the under spring should be the reverse of the curves of the deformity—opposing apex to apex. Thus the curve of the deformity and the curve of the combating spring should be so placed in contact with each other that when the centres are together and the curves drawn tightly toward each other there will be

reduction in exaggerated curves of the spine as well as the curves of the spring.

The curve of the back springs are opposed to the curves of the back (see Fig. 9) before the stays are brought together, but when the corset is tightened and secured to the figure (Fig. 10), its action is to flatten the dorsal curve in direct proportion to the strength of the springs.

For males, corsets are not so applicable for obvious reasons, and we therefore provide the springs with girths in such a manner as to be as effective for the purpose intended. So much for the mechanical treatment.

The physical treatment next engages our attention, and by this we mean the employment of such exercises and movements during the mechanical treatment as will conduce to the permanent cure of the deformity after the braces and corsets are thrown aside.

It is necessary in the first place to have a table, although a lounge or couch could be made to answer, the surface of which is padded or so covered as to be comfortable to the patient. This table should be a low one, so as to divest the patient of all fears of falling while undergoing treatment, and on such a table when the patient places himself there in the extension position—the edge of the table coming to the central dorsal region and the head and upper extremities hanging over—you will see that the chest has partially resumed its normal shape, that it has lost its contracted look, and that the shoulder-blades tend to approach each other. To

Fig. 9.

Fig. 10.

approximate these it is necessary to clasp the hands together behind and under him—and at first this is almost an impossibility. When undergoing this process it would appear as if the skin and tissues of the anterior of the thorax were stretched as much as their structure would allow, and that posteriorly the soft parts were redundant.

Dumb-bells of various weights are now taken in the hands and a series of rapid lateral movements practised which still further expand the chest. There are also quite a number of calisthenic exercises which are of advantage if practised in the backward traction position, but they must be employed with care and moderation, as their expanding effects are so powerfully augmented by gravity that they may strain the tissues painfully and thus delay treatment. A most useful agent is also found in the rubber-cord. Of these there should be two, fastened by detached hooks and staples to the floor in such a manner as to draw the hands beyond each other, the resistance of the muscles to the contractility of the rubber constituting a most valuable agent for developing the chest if formulated into a series of exercises.

This backward traction position may seem harsh exercise to be daily indulged in by your patients, but it is the most efficacious plan of physical treatment, and will do the most good in the shortest time. There are, however, many lighter forms of exercise which may be utilized.

One which can be specially recommended for other than the backward traction position is one in which the

chest is expanded by the body falling forward as much as the rubber cords grasped by the hands will allow, the feet not being moved and the head prevented from falling forward with the rest of the body (and thus the hyper-erect position maintained) by means of a wooden bar placed between the teeth and connected to a gymnastic frame by cord or wire. This is very serviceable also, in strengthening the muscles of the neck.

There are also certain postures which are of themselves beneficial, and should be recommended to your patients for their adoption.

The *first* is in regard to sleeping. Have both bolster and pillow removed from their usual place under the head, and have one or both placed under the shoulder-blades. This brings the head a little below the level of the dorsal region and curves the spine in direct reversal to the curves of the round shoulders; and as, during sleep, relaxation of the spine ensues, the posterior spinal muscles are permitted to recover some of the contractility they lose during the day if proper supports be not worn.

The *second* is that of reclining (not upon the back but upon the front of the body) during the day for reading or resting, the patient lying at full length and resting on the elbows. This is a favorite position with children and should be encouraged, as, if steadily practised, it is a sure preventive of the deformity. But many parents, instead of encouraging this trait, rebuke their children for it, and sharply order them to get up from the floor. If they could only be made to understand that it is one of the greatest helps to symmetrical development they would be more inclined to encourage its practice.

THE UNITED STATES MEDICAL SERVICE.

By CAPTAIN R. W. SHUFELDT,

MEDICAL CORPS, U. S. ARMY.

WHEN I speak of the United States Medical Service it is to be understood that the Medical Corps of the Army and Navy alone are referred to, the writer having little personal knowledge of the organization and government of the United States Hospital Marine, so that it would be through chance only that if anything we have to say here is found in the sequel to apply with equal force and pertinency to them.

With the Army and Navy of course it is different; the medical staff of the former being known to me as one of its members, and one who has performed the majority of such duties as are met with during the first seven years' service, and the schedule which forms the complete list is by no means as brief and simple in character as one might imagine. Connections of another nature have allowed me the opportunity to meet, and in many instances form lasting friendships with members of the medical staff of the Navy, and from the first impressions made on my youthful mind, while serving in the capacity of a young warrant officer aboard a man-of-war, during the year of 1864, by the surgeons of the fleet, memorably by Dr. Cassin, nephew of Cassin the naturalist, till such days of later years as those passed under Dr. Wales' personal tuition and guidance, to my present commission, have been of the happiest nature. So that, through this and other means, some opportunity has been afforded me of learning something of this service likewise.

Some of the questions I wish to call to the attention of the profession, and touch upon as best I may in an article that must necessarily be as brief as this one, were presented to my mind by an editorial that appeared in the *Philadelphia Medical Times* of May 7, 1881, entitled, "The United States Naval Medical Service," and several kindred articles that have appeared here, there, and elsewhere since. As the subjects to be discussed will be taken up in the order as they appeared in this editorial, it will be necessary for a clear understanding of the questions presented to quote here the entire first two

paragraphs of the remarks made by the editor of the *Medical Times*, leaving his two remaining columns to be handled in another way. He says: "It is probable that there is no medical government service in the world, the requirements for admission to which are more severe than is the ordeal through which the medical candidate for naval honors must pass in this country. We are credibly informed that twelve aspirants have been before the examining board now in session without one having succeeded. So far as a good deal of experience teaches us, we should say that the standard is even higher for the Navy than it is for the Army. Most of our readers will no doubt agree with us, however, that when once in the Navy a physician almost always disappears entirely from public sight, whereas in the Army not rarely he rises to a first rank among scientists. The doings of the medical staff of the Navy, what *are* they? A few reports lying upon book-shelves—pitiful pamphlets alongside the invaluable tomes that have come from the Surgeon-General's office at Washington. Not only is this true of medical works proper, but also of scientific publications other than medical. Where is the Dr. Coues of the Navy? Yet the abundant leisure, the months of floating in the tropics, the wide travel, afford both stimulant and opportunity for natural history research."

The fact that the editor of the *Medical Times* holds the opinion that the standard for entrance in the medical corps of the Navy is higher than it is in the Army, does not surprise me in the least. Nor is he to blame, for it is a very general, and I may say, an entirely erroneous one. It no doubt has arisen from the fact that the examination in the Navy is so arranged that it extends by custom or law through a full week, whereas in the Army a candidate may complete his examination successfully in from three to five days, depending altogether on how long it takes the board to satisfy themselves as to his fitness. The not unusual circumstance, the *Times* brings forward, of twelve young men failing before the Navy board, and still no successful candidate, is by no means a criterion, for instances have occurred in the Army where the sequence ran in between the thirties and forties before a successful candidate was found, and it stands to reason that if three medical gentlemen composing an examining board cannot ascertain the calibre of a man in from three to five days, they certainly will not do it in seven, or a month either as for that matter. Opportunity was afforded me, when I first entered the corps, for comparing the questions asked in examination for entrance to both services, and the impression was made upon me then that there was little or really no difference in their general character. In the Army the board is guided somewhat by the contents of the autobiographical letter that the candidate is obliged to write the first day of his examination, wherein he states what his general course of study has been up to the time of his appearance before the board. As an instance, in my own case, on my entrance examination I was requested by the board to submit to them for inspection specimens of skins of birds and mammals that formed a part of a collection I had made as a young man: they asked to see, likewise, colored drawings I had made of the same, as well as a set of marine charts that I had drawn to obtain an appointment as draughtsman in the United States Naval Hydrographic Office a year or two before. As the charts had passed me, and the specimens of birds had also been pronounced favorably upon by Professor Albert S. Bickmore, who was then in charge of the Museum at Central Park, New York, and had given me the appointment as naturalist to one of the Arctic expeditions then forming, I complied with the request of the board with more confidence than I might have under other circumstances. It would have been difficult, too, to have found expression for my delight in finding upon the very threshold of my new career such positive evidence that such pursuits were encouraged in the medical service of the Army.

Once in the corps of either service, after a certain length of time an officer is expected to pass a second examination before the examining board, the object ostensibly being to ascertain whether the officer is qualified for promotion or not. In former times in the Navy this examination was competitive and an officer could gain rank by it, but I believe such a pernicious feature as that must have been has now been done away with, though exactly how it is managed in these days I am not informed, but not long ago a surgeon of the Navy told me that under no circumstances did it threaten an officer's commission in any way.

In the Army this second examination is arranged on a widely different plan. Substantially the law says that after the first five years of an army medical officer's service, or what amounts to the same thing, after he has passed into the grade of captain, which he does by act of Congress at this time, he is liable to be called upon at any time to appear before the regular examining board to be examined as to his fitness for promotion. Should he be found in any way deficient a second trial is given him, after the expiration of a year; failing again, his resignation is requested.

When one comes to think of the effect that such a specification as this would have upon the mind of one engaged in the study of medicine, and the vast field of research that that means in our day, he will be struck at once by the fact that it affords drawbacks far more harmful in its ultimate effects than even the old competitive examination of the Navy. Speaking from my own personal experience with this second examination, I can say that during my first five years the impression had been made upon me, through conversation with many older medical officers, all of whom, as far as known to me, had been successful at this trial, that it was a matter of not much consequence, did not last long, and really was sort of a form to examine more into the question as to whether or no an officer had proved himself *generally fitted* for the service; an examination of his record. Many others held another view—showing that minds were divided on the question of its utility—that may be summed up in the expression given to it by one of the number, that “it was a sieve to catch the bad rats,” just as if medical officers were not amenable to trial by courts martial as any other staff officer for violations of the regulations of the service; or that a thing should exist that in its workings was harmful to the many while it acted with doubtful certainty in eliminating the few objectionable ones. Moreover, it is not believed that the Government ever intended to place such a power as this in the hands of a board composed of members of the same corps; still one's mind is harassed with the doubt if its object be to take a second look at an officer's attainments, when he sees medical gentlemen holding contract as acting-assistant surgeons at military posts appear before the board for examination for commission, be unfortunate in the attempt, yet return to their duties at military stations with the same responsibilities. This is not said as bearing at all upon the efficiency or non-efficiency of the gentlemen as a whole, for the writer holds many of them among his best tried friends, and in not a few instances members could be chosen from among their number that would be of the highest honor for any medical corps in the world to claim them as its own.

My mind had been lulled to a certain degree of security by what has already been cited above, in fact I was upon scientific duty in the Army Medical Museum at Washington, when the summons to this second ordeal reached me. I had made no *special* preparation whatever, so after a brief but exciting struggle of three hours failed. Comfort was dealt out to me that far abler men than myself had met the same fate and that it formed one of the episodes in the early life of Dr. Flint, of New York. It hardly seemed that this latter fact was anything to boast of, or proved the efficiency of the scheme to fulfil its purpose, if it had any. Before leaving New York, where

the board held its sessions, I met eight or ten medical officers of about my own date of entry into the service, who were there on the same mission as myself. Some of these gentlemen had passed, others had not been quite so fortunate, and still others had not yet been before the board and had been “cramming” there for three or four months. Naturally when we met the subject of the conversation turned upon the examination, and to make the matter brief, the unanimous verdict was that its effect was a *bad one*; that these effects may be prolonged over a period of from ten to fifteen years, as the law does not specify that one shall make his appearance positively at the end of the first five. A number of such instances are on record. The writer was doubly impressed with all the discussions that took place at these meetings, because he had just failed himself and now stood with the additional responsibility of a young family about him, with the fact staring him in the face that at the end of another year, should the same result follow, he would be asked to resign. Let us devote just a few words, however, to the chief drawback caused by this examination, and in fact the only one that interests the Government, whose aim it is to keep an efficient medical staff of the Army.

A young man is found qualified and enters the medical corps. As the preparation for his entrance examination has no doubt been trying, the first impulse after becoming accustomed to the novelty of freedom he at first experiences is to rest for a month or so; then follows a reading of the journals so generously furnished by the Surgeon-General's office; then a taking up again of his old text-books as cases commence to present themselves. Six or eight months glide by, when a never-out-of-the-mind fact, his second examination, commences to operate. In the mean time, no doubt, he has, as all professional men do, made a choice in the favor of some special subject or branch of his profession or undertaken some original line of research—perhaps because a uniform can never change the bent of a man's mind or human nature, however tightly it may be buttoned around him, as the history of numberless cases will vouch for. He may be in the very act of cutting a section for microscopical work, when it suddenly dawns upon his mind that very soon he is to be examined and the board may not touch upon this subject at all. This thought is followed by another, that he perhaps, if then called upon, could not give a very lucid explanation of the “cause of pitch of musical sounds.” He rushes to his works on physics; this subject barely opened when the first one comes up again, and the board may not care about the “pitch of musical sounds,” but about the “date and incidents of the battle of Crecy,” then the long vista of history is almost hopelessly scanned; but the board may not question him in history, although it is their prerogative to do so. At the end of an hour or so we find him leaning back in his chair, almost helplessly gazing at the four or five long rows of books before him, in a condition of mind totally unfitted for study, his tissue dried up on the slide, and the scalpel on the floor, or else he wanders out, and unless of cast-iron nerve, seeks other means, not professional, to drive this bugbear away, even for only a brief space of time, and yet this education of his mind may be kept up for years—receiving a *sudden* shock every now and then when he learns that some officer of undoubted ability has failed. Can any one devise a more perfect break to professional progress and excellence than this? anything more vicious in its operations, more certain to produce an irritability of mind and temper, a ranker poison to the hopes of a well-balanced education? Let any one—I care not who he is, or what position he holds—know positively and without reserve that at the end of some indefinite time he is to be examined, and perhaps his livelihood placed at stake, upon all branches of his many-faced profession and numerous not exactly specified collateral subjects, and he may be able to have some faint taste of the effect, but hardly appreciate it.

About a year ago, Surgeon J. H. Bill, U. S. Army, an earnest and able chemist, who for a long time was a member of the Army Medical Examining Board, published an article in *THE RECORD*,¹ which shows better the utter hopelessness of the situation, far better than anything that could ever come from my pen, or that I would ever hope to attempt. Dr. Bill presents his readers in this article with between twenty or twenty-five of the easiest questions his mind could suggest, and such as were propounded to candidates before the board, and as they are to illustrate a certain subject, they are all either physical or chemical. Now, easy though they be, and that depends much upon how the reader takes them, I will guarantee to make out *five thousand* such lists, containing an equal number of questions, and equally easy upon these subjects alone; not only that, but an equal number for anatomy, physiology, toxicology, hygiene, surgery, practice of medicine, obstetrics, materia medica, science, history, literature, medical jurisprudence, the eye and ear, and some half a dozen or more others. It is thus that doubts and complications arise in the mind of the student exactly where to begin. The beautiful vistas so aptly opened in the remainder of Dr. Bill's admirable article, and the advantages it points out accruing from a course of study in chemistry and physics, are equally applicable to like pursuits in several of the branches I have enumerated above.

Now that the writer has run safely through this hit-or-miss gauntlet, having passed at his second trial, he is free to confess that this second examination is the greatest drawback that the medical officer has to contend with, and it constantly risks injuring many a mind. On general principles, I do not believe in examinations, to any great extent, any way. Of my six years' college course those studies that were not followed by an examination at the end of the term have always been better remembered and of the greatest service to me, and I doubt not but that this has been the experience of others.

Professor Huxley has so much to say upon this subject² that is wholesome, pertinent to the question, and bears upon what we will have to say in a moment, that I will take the liberty of quoting quite extensively from him. He remarks that: "Examination, thorough, searching examination, is an indispensable accompaniment of teaching; but I am almost inclined to commit myself to the very heterodox proposition that it is a necessary evil. I am a very old examiner, having, for some twenty years past been occupied with examinations on a considerable scale of all sorts and conditions of men, and women too; from the boys and girls of elementary schools to the candidates for honors and fellowships in the Universities. I will not say that in this case, as in so many others, the adage, that familiarity breeds contempt, holds good; but my admiration for the existing system of examination and its products does not wax warmer as I see more of it. Examination, like fire, is a good servant, but a bad master. I by no means stand alone in this opinion. Experienced friends of mine do not hesitate to say that students whose career they watch, appear to them to become deteriorated by the constant effort to pass this or that examination, just as we hear of men's brains becoming affected by the daily necessity of catching a train. They work to pass, not to know; and outraged science takes her revenge. They do pass, and they don't know. I have passed sundry examinations in my time, not without credit, and I confess I am ashamed to think how very little real knowledge underlay the torrent of stuff which I was able to pour out on paper. In fact, that which examination, as ordinarily conducted, tests, is simply a man's power of work under stimulus, and his capacity for rapidly and clearly producing that which, for the time, he has got into his mind."

Then after setting forth much more that is true of the question, he concludes with this paragraph:

"No doubt a great deal is to be done by careful selection of examiners, and by the copious introduction of practical work, to remove the evils inseparable from examination; but, under the circumstances, I believe that examination will remain but an imperfect test of knowledge, and a still more imperfect test of capacity, while it tells next to nothing about a man's power as an investigator."

So much for the standards of the examination of the two services, and so much for the examinations themselves.

Turning again to the editorial of the *Medical Times*, we find that at the remainder of the article, both such parts of it as we have quoted above and the unquoted portion, essentially calls attention to two things. The first of these is—Why is it that naval medical officers so seldom arrive at any degree of prominence, and of a consequence the naval medical corps is not a celebrated one, and rarely produces large standard works upon scientific and professional subjects; whereas the medical corps of the Army, not rarely has an officer of distinguished scientific or professional ability appear in its ranks, and as of a natural consequence the medical corps of the Army has become famous throughout the world, and the immense number of its publications are ranked as standard and classical works, both in medicine and science? The second question, to which the reader's attention is called, is the cause or especial reason for these things.

The *Times* confines its discussion of the causes for this, in a desultory sort of a way, to the naval side of the question, suggesting two reasons—the first, "that salt air is a veritable lotus-flower, soothing into an irresistible indolence him who breathes its miasm;" the second, the short length of time that the Surgeon-General of the Navy holds his position. Both of these reasons bear with them a great deal that is true.

In the first case it is not so much the soothing influence of the salt air, as it is that "a rolling stone gathers no moss;" the exceedingly cramped space that one has to work in aboard ship, the limited appliances and books, the action of salt water and air in destroying these, more or less motion of the ship at nearly all times, the noise and excitement in port, and all such matters are eminently antagonistic to long and painstaking research, from which alone flow such volumes as the editor of the *Medical Times* so complimentarily alludes to as having been produced by medical officers of the Army. It might be asked, How is it, then, that such explorers as Darwin ("Five Years at Sea in the Beagle"), Wallace and Bickmore ("In the Malay Archipelago"), and numberless others, have produced such beautiful works as the result of their explorations? It must be remembered that these gentlemen start out thoroughly equipped for the work, that the ship is practically given up to their collections, and the books are written at home during the many years of quiet life that follows.

With reference to the short term of office of the Surgeon-General of the Navy, as being one of the causes militating against the production of extensive scientific work in the corps, the editor has evidently hit one of the principal nails on the head, and his question—"How long would any business enterprise thrive whose management was changed every year or two?"—is easily answered. We may say here, too, that little risk was attached to his prediction, and it has since proved true, as to what the history of the medical corps of the Navy would do under the wise regime of Dr. Wales. This able thinker and author, at once gathered those about him of his corps, who had shown special aptitude for either medicine or science, upon some occasion or another, and the effect was immediately apparent in the birth of the Naval Medical and Surgical Society of Washington, with its museum and the scientific and professional papers of numerous medical officers, all of which will pass Dr. Wales' detail down into the history of the medical corps of the Navy, as one of the most advanced and highest

¹ A Plea for a More Thorough Study of Chemistry in Medicine and the Arts, by J. H. Bill, M.D., Surgeon U. S. Army. *MEDICAL RECORD*, vol. 22, No. 7, August 12, 1882, p. 175.

² Science and Culture and other Essays, by T. H. Huxley, p. 67. 1882.

of its epochs, and one to which his name will be forever linked.

When the editor of the *Medical Times* asks the question, as he does in the paragraph we have quoted, "Where is the Dr. Coues of the Navy?" it seems to carry with it that such geniuses are the creation of the Army or the Navy, *per se*, whereas such by no means is the case. The Navy has been, so far, unfortunate, notwithstanding the fact that they employ the same means that the Army does, in not having captured such a mind to add lustre and fame to their corps, for it is through the scientific works of such men that any organization becomes famous; or, indeed, known at all. Is it surprising that when we have a board composed of three or four cultured men, sitting almost continuously throughout the year, and in that time examining from one hundred to two hundred young men, graduates of medicine, and often of the highest classical universities in our land; in short, having the pick of the best material of such a vast country as ours, that they should occasionally find a genius in their net? Never lose sight of the fact that Dr. Coues would have been Dr. Coues anyway; that Dr. Billings would have been Dr. Billings anyway, and so on for such lights as our Drs. Woodward, and Otis, and Beaumont; and, undoubtedly, I could have added Dr. Flint, but he slipped through the meshes, though he *has* been Dr. Flint anyway. Such minds are the outcome of our civilization, and they are no more the property of the Army than they are of our noble country at large. All the Army can do—or, perhaps, I had better say the Government—is to see well to it, for the credit of our country, that the soil on which she places such men is adapted to their growth and not to their death; or, what is almost as bad, if not actually worse, where they become distorted and stunted shrubs, of no credit to anybody. That the Government does not always do this Dr. Coues himself will tell you.¹

It is the bristling front of our entrance examination that guards the portals to our corps, like Leonidas did the Thermopylean pass, that makes it possible to add such men to our number, and it is a matter in the hands of the Government afterward whether the country gets the greatest amount of good out of them. Remove this safeguard and the countless horde of Persians would in a twinkling annihilate our fame, and our little body of three hundred and a few odd would sink out of sight and be no more heard of than an equal number chosen at large over our vast frontier.

Emerson has shown us, as only he could, how such geniuses are produced;² and Huxley clearly defines their rarity when he tells us "but a small percentage of the population is born with that most excellent quality, a desire for excellence, or with special aptitudes of some sort or another. Mr. Galton tells us that not more than one in four thousand may be expected to attain distinction, and not more than one in a million some share of that intensity of instinctive aptitude, that burning thirst for excellence, which is called genius. Now, the most important object of all educational schemes is to catch these exceptional people and turn them to account for the good of society. No man can say where they will crop up; like their opposites, the fools and knaves, they appear sometimes in the palace and sometimes in the hovel; but the great thing to be aimed at—I was almost going to say the most important end of all social arrangements—is to keep these glorious sports of nature from being either corrupted by luxury or starved by poverty, and to put them into the position in which they can do the work for which they are specially fitted. Thus, if a lad in an elementary school showed signs of special capacity I would try to provide him with the

means of continuing his education after his daily working life had begun; if, in the evening classes, he developed special capabilities in the direction of science or of drawing, I would try to secure him an apprenticeship to some trade in which those powers would have applicability. Or, if he chose to become a teacher, he should have the chance of so doing. Finally, to the lad of genius, the one in a million, I would make accessible the highest and most complete training the country could afford. Whatever that might cost, depend upon it the investment would be a good one. I weigh my words when I say that if the nation could purchase a potential Watt, or Davy, or Faraday, at the cost of a hundred thousand pounds down, he would be dirt-cheap at the money. It is a mere commonplace and everyday piece of knowledge that what these three men did has produced untold millions of wealth, in the narrowest economical sense of the word."³

Quite recently an officer expressed his surprise to me that Dr. Billings ever made the renowned bibliographer that he is. "Why," he said, "when I first knew him he was doing scarcely anything except looking at fungi through a microscope!" "Sir," I could only reply, "your surprise is no greater, probably, than that of many other officers of every branch of the service, who have said of Dr. Coues, in the early days of his scientific work, that 'he was working to the detriment of his profession,' and many other such sentiments, when Dr. Coues to-day fills with the highest credit the chair of anatomy, the study which is the foundation of all medicine, in a university that nearly every year supplies one or two young officers to the medical corps of the Army and Navy."

For the growth of medicine and science let us do all we can to prevent the rendering axiomatic of Dean Swift's famous phrase, "When a great genius appears in the world the dunces are all in confederacy against him."

It is impossible to tell, from such biological studies as a young man may take up in the early part of his career, where they will land him; and it is more than likely that a great deal of his work will come to be of practical utility—some day. To support this one has to think but for an instant, and the intelligent physician and scientist not at all, what the knowledge of the anatomy of mammals, birds, reptiles, or, in fact, any of the lower orders of vertebrates has done for our science of medicine.

It will be granted that a knowledge of the anatomy of the form operated on is essential before many of those facts could be demonstrated that require such delicate manipulation, and upon which nearly all of our great truths in physiology depend. Let any one take either of those magnificent volumes of Dr. Flint or Dr. Dalton and clip out, with a pair of scissors, all such parts as where a knowledge of the anatomy of the vertebrates is required in some way or another, or where our knowledge of some physiological truth has been obtained through such media, and note the shrinkage. We all know that our *science* of medicine hangs upon the four fundamental branches of anatomy, physiology, chemistry, and physics. Now what would become of this science if the experiment I have just mentioned could be applied to all such literature back to the days of Aristotle? Simply that the science of medicine would travel backward half that distance itself, to put the mildest construction on it.

In conclusion let us wish that during these long days of peace the many changes required in the medical service of the Navy may be brought about, such as the establishment of their actual rank by act of Congress, as it is in the Army, so that a medical officer may command in his own sphere of action, and that the term of surgeon-generalship be made for a longer term of years—for reasons we have already set forth.

It is to be hoped, that with us in the Army, the requirements of the first examination be, if anything, made still more rigid, more searching into the moral, mental,

¹ A Criticism, by Dr. Elliott Coues, in the *Nuttall Ornithological Bulletin*, Cambridge, Mass., vol. viii., July, 1883, page 166, on Contributions to the Anatomy of Birds, by R. W. Shufeldt, M.D. [etc.], author's edition, extracted (in advance) from the Twelfth Annual Report of the late United States Geological and Geographical Survey of the Territories (Hayden's). 8vo, title and pp. 593-806, plates i.-xxiv., many woodcuts in text. Washington: Government Printing Office, October 14, 1882.

³ *Science and Culture*, p. 90.

and physical attainments and conditions of the candidates presenting themselves; in short, of so severe a nature as to annihilate the second examination, and render the necessity for its very existence useless; that the present retirement bill, or any other act of Congress, will ever operate so as to prevent the Surgeon-General from holding his office for a less period than twelve or fifteen years, and that he will be chosen, as heretofore, for his executive ability or professional and scientific attainments; that encouragement will always be extended to those who have shown special excellence and progress in professional or scientific work. And one other matter which my space has not allowed me to refer to, is that the day is not far distant when we will see a separate, beautiful in point of design, and substantial edifice shielding our many thousand volumes of valuable professional books, our chemical laboratory, and a museum of surgery, medicine, and comparative anatomy, of which Eric Erichsen has said, after he had reviewed it in its present tumble-down building: "Ah! gentlemen, we have nothing like this in England!"

TREATMENT OF TYPHOID FEVER.¹

By I. P. KLINGENSMITH, M.D.,

DERRY STATION, PA.

EX-PRESIDENT WESTMORELAND (PA.) COUNTY MEDICAL SOCIETY.

THE object of this paper is not to enter into the history, pathology, and etiology of the disease in question, but to bring before the Society a method of managing typhoid fever as employed in my practice during the past two years, and which has yielded most satisfactory results in the cases in which it has been carried out. In order to economize time and bring the subject more fully before you at once, I will proceed to sketch the plan of treatment briefly:

When I find the patient to have typhoid fever, or when his symptoms indicate that the disease is about to develop, I order him to bed and put him on a liquid diet consisting of milk, beef-tea, or animal broths. I then order the following mixture, as recommended by Bartholow:

R. Tr. iodinii 3 ij.
Acidi carbolici 3 j.

M.

Of this mixture I direct three drops to be given in a wineglassful of iced or cold water, three times daily, after meals, and which is continued until convalescence is well established. As a rule this medicine is well borne by the stomach, and occasions no disgust on the part of the patient. Partly for its favorable influence upon the skin, for the sake of cleanliness, and also the slight influence upon the temperature, the patient is sponged twice daily with equal parts of alcohol and water, or in some cases, where more grateful to him, with tepid water.

When I find the evening temperature to reach 103° F. quinine in large doses is administered, upon a falling temperature. I usually direct at least thirty grains to be given, one-half the quantity at 5 A.M., and remainder if deemed necessary at 5.30 or 6 A.M.

This quantity, as a rule, will lower the temperature from 2.5° to 3.5° for the next forty-eight hours, after which it may be found necessary to repeat the medicine. In a few cases where the temperature has reached 106° F. I have given quinine amounting to fifty and even sixty grains, succeeding most happily in reducing the temperature without any sustenance of injury to the patient.

For the relief of the headache in the early stage of the disease I find the following to answer the indications:

R. Quiniæ sulph gr. ij.
Ex. belladon gr. ¼

M. et ft. in pilula. Sig.—One pill every three or four hours.

Alcohol is not often indicated until after the close of the third week, unless by reason of the habits of certain patients it may be necessary throughout the attack. In the event of heart-failure it must be administered according to the exigencies of the particular case. A majority of patients do well without taking it at all. Should the diarrhœa become excessive I direct a pill as follows:

R. Argenti nitratis gr. ⅓.
Pulv. opii gr. j.

M.

To be given every four hours until brought under proper control. On the other hand, should obstinate constipation intervene, I never hesitate to give a dose of calomel, unless there are reasons to suspect serious intestinal lesions, in which event the bowels may be emptied by enemata.

To prevent hypostatic congestion of the lungs, the patient is turned upon his side from time to time. As an invariable rule from the recognition of the disease the patient must maintain the horizontal position until convalescence is well established.

During the sickness the patient should have a competent nurse, whose duty it is to attend to the punctual administration of the medicines and diet. A liquid diet, consisting of milk, beef-tea, or other animal broths, must be given every two or three hours. Perfect quiet must be maintained in the sick room, all visitors being positively excluded. The room should be kept darkened, all pictures and paintings removed from the walls, and the medicines kept out of sight of the patient. Perfect ventilation must be secured. To avoid establishing a focus of contagion, the dejections must be systematically disinfected immediately after being voided.

The total number of cases treated by this plan is fifty-two, with a recovery of all. Of the cases, twenty-eight were severe, the temperature in three reaching 106° F., and in the other twenty-five 103.5° to 104°. In three of the cases a mild attack of rheumatism set in during convalescence. In two cases a severe relapse from indiscretion in diet prolonged the disease. The average duration of the severe cases was about thirty days, and of the milder about twenty-six days.

You will observe that the remedy employed is iodine in combination with carbolic acid, which no doubt prevents the multiplication of germs in the intestines, checks fermentation, and maintains an antiseptic action in the blood. Also the judicious administration of quinine in doses sufficient to control the temperature.

The success attending this plan of treatment in my hands encourages me to continue it further; and, in conclusion, I will say in its behalf that any who may give it a fair trial will be favorably impressed, and feel that they have put a different complexion on the statistics of mortality.

THE SALE OF IMPURE CREAM OF TARTAR.—A conviction was recently had in the Court of Special Sessions of this city for a violation of the Food and Drug Adulteration Law of 1881, in the sale of an impure article of cream of tartar. Only a small fine was imposed; but as the cream of tartar had not been sold as a drug but by a grocer in the course of his trade, it was thought of sufficient importance to appeal. This was done, and not long since the conviction was reversed, the Court holding that where the defendant proved that he had bought the cream of tartar sold by him from a dealer in the open market; that before buying it he had inquired for the best article, and had been told by the dealer that what he purchased was the best; that he paid the highest market price for it, and believed that he was purchasing a pure article and the best, and that he sold it believing it was a pure article. Under these circumstances no criminal intent or criminal negligence had been made out and no offence proved.

¹ Read before the Westmoreland County (Pa.) Medical Society, May 1, 1883.

PEROXIDE OF HYDROGEN IN PURULENT INFLAMMATIONS OF THE EYE.

By LE ROY POPE WALKER, M.D.,

HOUSE SURGEON NEW YORK EYE AND EAR INFIRMARY.

FOR the introduction of peroxide of hydrogen in ophthalmic practice, we are indebted to Landolt, who, after an extended and careful trial proves it to be of undoubtedly great value.

In a very able paper on the subject (*Archives d'Ophthalmologie*, September and October, 1882) he gives a large amount of highly interesting information concerning the properties of hydrogen peroxide which it would be well for those wishing to try its effects to read.

"Peroxide of hydrogen (H_2O_2) is ordinarily prepared by the action of dilute acids on the peroxides of the alkaline earths. The hydrated peroxide of barium is decomposed by dilute sulphuric acid, so as to form sulphate of barium and peroxide of hydrogen. The solution obtained in this way contains three per cent. of its weight of pure peroxide of hydrogen, and is sufficiently strong for medical purposes. The dilute solution is a clear, colorless, inodorous liquid, with a taste something like that of cress" (*Ophthalmic Review*).

It is said to retain its properties unaltered for years, if kept at a temperature below $70^\circ F.$ and well protected from light. It should also be well stoppered, as it rapidly deteriorates if exposed to the air. One of the peculiarities of hydrogen peroxide is the readiness with which it yields free oxygen.

Pus is one of the many substances remarkable for the energy with which it causes the liberation of oxygen. Hydrogen peroxide is also a powerful agent in preventing and arresting fermentation. "It is probable that the peroxide of hydrogen when subjected to the catalytic action of bacteria, reacts upon them and renders them inert. Excellent results have been obtained in the treatment of wounds by this substance."

For the eye it has special advantages as an antiseptic; for, unlike many other so-called antiseptics—notably carbolic acid, bichloride of mercury, alcohol, salicylic acid, etc.—it can be used without danger, and of sufficient strength to be effective.

"When the solution is applied to a conjunctiva affected with purulent inflammation, a froth, resulting from its catalysis by the secretion is instantly produced. The inflammatory products are not destroyed by it, but their physical condition is so altered that they are readily removed from the inflamed surface and all septic action arrested, the micro-organisms in the pus being killed by the nascent oxygen. The conjunctiva, examined ten minutes after the application, is found covered with a layer of fibrin which will again catalyse the solution. After two or three applications the exudation is much diminished, and with each repetition the froth becomes less and less until it is hardly formed at all; pathological secretion is then at an end."

The application produces a sensation of pricking and burning, amounting often to severe pain, which, however, soon passes off. It has been found speedily effective in purulent conjunctivitis, in which boracic acid and iodoform had been tried without result.

In cases of corneal ulcer, with purulent infiltration, its action has been surprisingly good. In fact, it has been my experience that it is much more potent in corneal processes than affections of the conjunctiva. Landolt's method of using it is to instil a few drops of the solution into the conjunctival sac two or three times in an hour, at intervals of ten or fifteen minutes, bringing the solution thoroughly into contact with the affected surface.

I have found it fully as effective when used once in two hours, instilling a dozen to fifteen drops at a time, and much less irritating than when used after the manner of Landolt, for it is to a certain extent an irritant, and its too frequent application may prevent the beneficial results which it is desired to obtain. I also take the pre-

caution to thoroughly cleanse the parts with a saturated solution of boracic acid, before again using it, and if this is not sufficient I remove the layer of fibrin with a delicate pair of forceps.

In purulent ophthalmia, after an abatement of the secretion, I have found it best to discontinue the use of the hydrogen peroxide, as its action is now nil, and a return to its use should not be made unless there be a return of the purulent secretion.

Landolt has met with very great success with this remedy in the treatment of suppuration of the lachrymal passages, and considers it vastly superior to bichloride of mercury, boracic acid, etc.

The subjoined cases, will, I think, go far to prove the efficacy of peroxide of hydrogen in ulcerative and purulent processes in the eye. A solution was obtained in April, 1883, by Professor H. D. Noyes, and at his suggestion I first tried it in a number of cases in his service. Since then I have had the opportunity of observing its good effects in cases occurring in the practice of other members of the staff, and by their courtesy I am enabled to present the following notes:

CASE I. (Hospital No. 7,026).—J. R.—, male, aged thirty-five; admitted June 1, 1883 (service Dr. Callan). General health good. Examination showed a large serpiginous ulcer in the centre of the cornea. Pain and great photophobia. Ordered hot applications constantly and a solution of atropia (grs. ij. to $\frac{5}{8}$ j.) t. i. d.

Second day.—Corneal process extending, and threatening to perforate. A Saemisch section was done, carrying the knife entirely across the cornea, and through the centre of ulcer.

Seventh day.—Eye showing no signs of improvement, a solution of hydrogen peroxide (one per cent.) was instilled every two hours, and atropia t. i. d.; heat continued.

Ninth day (second of hydrogen peroxide).—Process arrested, and edges of ulcer clear cut and surface clean. Patient entirely free from pain.

Thirteenth day (third of hydrogen peroxide).—Ulcer healing rapidly. Injection disappearing.

Fourteenth day (fourth of hydrogen peroxide).—Patient left hospital, with directions to occasionally use solution of peroxide of hydrogen at home. Came back three weeks later to report. Ulcer entirely healed, and only a small macula remaining, as evidence of previous trouble.

CASE II. (Hospital No. 7,757).—A. C.—, male, aged twenty; admitted June 22, 1883 (service Dr. Moore), with a gonorrhœal ophthalmia of left eye, of forty-eight hours' standing. General health fair. Both lids much swollen and bathed in pus; chemosis marked, and cornea slightly hazy. Right eye immediately sealed with a watch-glass, for protection. Lids of affected eye were touched with a ten-grain solution of silver, and a one per cent. solution of peroxide of hydrogen was instilled every half hour. Atropia (grs. ij. to $\frac{5}{8}$ j.) t. i. d., and ice compresses constantly.

Second day.—Secretion much diminished, swelling, and tension of lids less, and corneal process arrested. Solution of hydrogen peroxide now instilled every hour.

Third day.—Swelling of lids steadily decreasing; chemosis much less and secretion reduced fully one-half; cornea clear. Patient free from pain. A saturated solution of boracic acid has been injected between lids every half hour. Solution of silver continued once daily.

Fifth day.—Patient is now able to open eye to a limited extent, and swelling of lids, chemosis, and secretion rapidly disappearing.

Ninth day.—Solution of hydrogen peroxide discontinued, as secretion had entirely ceased, and cornea remained clear. Is now able to open eye fully one-half. Cold, silver, and atropia continued.

Thirteenth day.—The solution of silver, grs. x. to $\frac{5}{8}$ j., changed to a solution of grs. v. to $\frac{5}{8}$ j. Ice applied four

times daily, for half an hour at a time, instead of constantly, as heretofore. Atropia twice a day, and solution of boracic acid injected between lids once every three hours. Injection of conjunctiva nearly all gone.

Eighteenth day.—Ice discontinued and a cold solution of boracic acid substituted, to be used t. i. d. Solution of silver (grs. v.) continued, to prevent granulations.

Twenty-second day.—Patient discharged entirely cured. Cornea without a blemish.

CASE III. (Hospital No. 8,086).—D. G——, male, aged fifty; admitted June 30, 1883 (service Dr. Callan), with a central ulcer of cornea. Patient run down and suffering from chronic malarial poisoning. Was put on use of hydrogen peroxide (one per cent.) immediately, instillations every three hours, atropia (grs. ij. $\frac{3}{4}$ j.) t. i. d., and quinia sulph. (grs. v.) twice a day.

Third day.—Ulcerative process arrested and evidences of repair beginning. Patient free from pain.

Fifth day.—Patient left hospital, well on way to complete recovery.

CASE IV. (Hospital No. 8,168).—A. W——, female, aged twenty-nine; admitted July 5, 1883 (service Dr. Moore), with a gonorrheal ophthalmia of both eyes. In right eye ophthalmia of three, and in left of two days' duration. General health good. Lids of both eyes tense and much swollen; abundant secretion; chemosis marked, especially in right eye; cornea of right eye hazy; cornea of left eye clear. Finding great difficulty in evertng lids, and owing to pressure on cornea, a double cantholysis was done immediately, followed by free hemorrhage, which was encouraged. The lids of both eyes were touched with a ten-grain solution of silver, and ice compresses ordered constantly. Atropia (grs. ij. $\frac{3}{4}$ j.) t. i. d., and solution of hydrogen peroxide (one per cent.) instilled in both eyes every hour. Every half hour a saturated solution of boracic acid was injected between the lids.

Second day.—Secretion much less and swelling of lids reduced; no pain; cornea of right eye slightly more hazy; cornea of left eye clear; chemosis in both eyes much the same.

Fourth day.—A small ulcer developed in right eye, but haziness, which two days previous had been rather diffuse, now limited and of superficial character; cornea of left eye clear and chemosis nearly all gone; very little secretion, and swelling of lids much reduced. Solution of silver discontinued in left eye.

Sixth day.—Ulcerative process confined, but the haziness again extending over upper portion of cornea of right eye. Ice changed to hot applications, and hydrogen peroxide (three per cent.) instilled hourly. Left eye steadily improving; no secretion; lids of normal thickness, and patient is able to open her eye.

Seventh day.—In right eye secretion much increased by heat, but ulcer looks better and is not extending. The slight haziness observed day before gone. Left eye doing as well as possible; ice continued occasionally.

Twelfth day.—Ulcer in right eye much improved and secretion rapidly disappearing; swelling of lids and chemosis less; silver discontinued. Left eye practically well, only a slight injection remaining.

Seventeenth day.—No secretion from right eye. No chemosis, and swelling of lids all gone. Ulcer shows signs of healing. Able to open eye one-half. Heat, atropia, and hydrogen peroxide continued.

Eighteenth day.—Conditions much the same. Solution hydrogen peroxide discontinued. Boracic acid solution (saturated) injected between lids every hour.

Twentieth day.—Ulcer nearly well; very little injection; able to open one eye fully. Heat applied twice a day; atropia, t. i. d. and solution boracic acid four times daily. Left eye entirely well.

Twenty-first day.—Ulcer healed, and only evidence of disease remaining is a slight conjunctival injection. All treatment stopped.

CASE V. (Hospital No. 8,418).—M. J——, female,

aged twenty-five; admitted July 13, 1883 (service of Dr. Minor), with a suppurative keratitis of left eye, involving entire cornea, result of burn from chloride of lime. General health good. A Saemisch section was made, carrying cut entirely across cornea, thereby liberating a large quantity of pus, which entirely filled lower two-thirds of anterior chamber. A solution of hydrogen peroxide (one per cent.) was ordered instilled every two hours; hot applications constantly and atropia (grs. ij. to $\frac{3}{4}$ j.) t. i. d.

Second day.—Cornea, which yesterday it was feared would slough away as a whole, now shows signs of clearing and the patient is free from pain.

Third day.—Corneal suppuration is arrested and is gradually clearing, especially in upper and outer margin.

Ninth day.—The cornea has steadily cleared and the iris is distinctly visible through upper half. Instillations of hydrogen peroxide continued every two hours and atropia and hot applications as before.

Tenth day.—Lower portion of cornea is now clear and there only remains a small central spot that is cloudy. Injection rapidly disappearing and the patient is able to open her eye fully.

Twelfth day.—Very slight injection remaining and eye well.

FOREIGN BODY IN THE TRACHEA OF AN INFANT EIGHT MONTHS OLD—TRACHEOTOMY—RECOVERY.

By A. SCHAPRINGER, M.D.,

NEW YORK.

JAMES M——, eight months old, of 345 East Sixtieth Street, was brought to my office on June 6, 1883, on account of alarming dyspnoea which had supervened suddenly the same morning while he was eating a slice of an orange. The child had first been taken to a neighboring drug store, where a dose of syrup of ipecac was administered. This brought about vomiting, without, however, relieving the dyspnoea. When first seen by me, the child was cyanosed. Both inspiration and expiration were labored. Auscultation over the trachea revealed a rattling sound both on inspiration and expiration. The latter was brought to a sudden stop, a peculiar click. The rattling was perceptible to the touch also. These signs left no doubt as to the presence of a movable obstruction in the windpipe. After a few ineffectual attempts to remove it by inversion, the child's condition in the meanwhile becoming more and more alarming, I performed tracheotomy, assisted by Dr. A. Fridenberg and Messrs. Tynberg and Schulmann, students of medicine. The child was given a few whiffs of chloroform. The hemorrhage was slight, but one vessel requiring to be secured. The trachea was scarcely opened when the foreign body was expelled through the perforation by a fit of coughing. It proved to be an orange-pit. Regularity of respiration not becoming re-established after the lapse of a few minutes, a flexible catheter was introduced and a small quantity of blood and mucus removed by aspiration. In about twenty minutes the child had so far recovered that I could proceed to close the wound. I first united the lips of the tracheal incision by a few silk sutures, and carried the ends of the threads through both the upper and lower angle of the integumentary incision, which I closed by a separate row of sutures. I avoided including the mucous membrane in the tracheal sutures. Catgut, which would have been preferable to silk, was not accessible. The wound healed by first intention, with the exception of the angles where the threads of the deep sutures had been led out. These could be removed after the lapse of a few days. The little one has been well ever since.

The interest of this case centres in the fact that there is no record, in this country at least, of so young a child having survived tracheotomy for the removal of a foreign body.

226 EAST SIXTIETH STREET.

ON THE TREATMENT OF EPILEPSY.¹

BY PROFESSOR DUJARDIN-BEAUMETZ,

MEMBER OF THE ACADEMY OF MEDICINE, AND PHYSICIAN TO THE HÔPITAL
ST. ANTOINE, PARIS, FRANCE.

GENTLEMEN: I devote this lecture to the treatment of that most formidable of the neuroses—epilepsy. When we survey the numerous remedies which have been proposed for this disease—remedies often uncertain and inefficacious—we easily comprehend the discouragement and despair of many physicians who have pronounced epilepsy incurable; moreover we see why the ancients attributed a divine origin to this affection, for to them the words *morbus sacer*, *morbus divinus*, testified sufficiently that the disease was generally above the resources of their art. But this feeling of discouragement ought no longer to exist. We have already found in the bromides a remedial agent which enables us to cure one half our epileptic patients, and we may be permitted to indulge the hope that some day we shall find a remedy still more powerful, which shall give us complete mastery of the disease. For this end we shall labor, and with all zeal.

It may almost be said that every medicine under heaven has at one time or another been prescribed for epilepsy. Do not then expect from me an enumeration of this long list of medicaments; I shall merely touch upon a few of them to lay particular stress on such as experience has proved efficacious. To give some system to my exposition, I shall divide the treatment of epilepsy into two parts: first, general treatment; second, treatment of the attack. In order to grasp the principles of the general treatment it is necessary to enter somewhat into details respecting the pathogeny of this affection. Sometimes epilepsy is manifestly dependent on a lesion of the nervous system, it is then symptomatic; sometimes no lesion is apparent, and we call the epilepsy essential.

As for symptomatic epilepsy, experimental physiology and clinical observation have given us certain proofs of the influence of lesions of the nervous system on the development of this neurosis. Brown-Séquard by his curious experiments on guinea-pigs has shown us that epilepsy may be produced by section or ablation of the sciatic nerves, and what is stranger and still more inexplicable, that this experimental epilepsy affects not only the animal so mutilated, but also its offspring, so that epileptic guinea-pigs, in consequence of lesions of the sciatic nerves, ever afterward have epileptic progeny.

The same symptoms are produced in certain lesions of the spinal marrow or cerebrum. Westphal rendered guinea-pigs epileptic by blows on their heads. Hitzig, Eulenbarg, and Landois by irritating the motor cortical centres of animals by mechanical and chemical agents, and by electricity, brought on attacks of epilepsy. Points have been localized in the cerebro-spinal axis whose excitation produces epilepsy, and Albertoni and Koloman-Balogh have given precise directions in this regard. Roberts Bartholow has gone even farther, and in a patient the surface of whose brain was denuded to some extent, he has produced epileptiform convulsions by applying electricity to the exposed cortical substance.² Clinical observation strikingly confirms these experimental facts, and the annals of medicine contain a vast number of cases where wounds and irritations of nerves have determined epilepsy, and where it has sufficed to remove the vicious cicatrix, or the foreign body embedded in the tissues, in order to obtain a permanent cure. In other instances the epilepsy has resulted from injuries or compressions of the cerebral substance, by spiculae of

bone, by abscess, by tumors; the removal of the bony splinters or the disappearance of the tumors has brought about complete cure.

It is in cases of this kind that the application of the trepan in the treatment of symptomatic epilepsy gives good results. Extolled by the ancients in an empirical fashion, the trepan has of late years found its legitimate place, a place, in fact, of such importance that we have seen in America an eminent surgeon perform this operation for the cure of epilepsy twenty-three times in five years, and obtain seven complete recoveries. Echeverria, in his interesting statistics, gives the results of one hundred and forty-five cases, ninety-three of which were permanently cured by the trepan.¹

In the same group we place anti-syphilitic medication, for oftentimes the relation which exists between this neurosis and syphilis is explained by the presence of gummata, or bony tumors compressing the brain and spine, and it is quite clear, as Fournier and Dreschfeld have shown, that in cases of this sort the specific is the proper treatment for the neurosis. In this same category we must place epileptiform convulsions due to the presence of worms in the intestines, and which disappear with the expulsion of the offending cause. In this group, too, we must place those cases of epilepsy connected with troubles of the genital functions, for the relief of which Marshall Hall proposed castration.

It was formerly maintained that epilepsy results from a chronic inflammation of the brain and spinal cord; a variety of epilepsy even was described under the name of plethoric epilepsy. Morgagni, Fothergill, and others defended this doctrine of the constant inflammatory origin of epilepsy, hence their antiphlogistic treatment, which consisted in blood-letting and the most powerful derivatives, such as cauteries, blisters, and setons. This kind of treatment is now a thing of the past; it gave no certain results of any value, and was based on a hypothesis which the recent anatomo-pathological researches on essential epilepsy have not confirmed.

We know that since the labors of Schroeder-Van der Kolk and Echeverria, the post-mortem disclosures in deaths from epilepsy have generally been alterations of the medulla oblongata, characterized by an intercellular albuminous exudation and capillary ectases. It may, however, be reasonably affirmed that these lesions are the consequence rather than the cause of attacks of epilepsy. Nevertheless, the rachidian bulb has a predominant part in epilepsy, and it is by modifications of its functions that we best explain the convulsive paroxysms.

The first phase of the attack, that which corresponds to the initial outcry, to the loss of consciousness, and to the tetanic contraction of all the muscles of the economy, would seem to result from an excitation of the medulla oblongata, sufficient to cause sudden anæmia of the cerebrum and of the bulb itself. Next comes the asphyxia, consequence of this tetanic state, and the passive congestion of the cerebro-spinal axis which it produces. Next in order is a period of reaction, in which the accumulation of venous blood in the encephalon and spinal cord determines clonic convulsions everywhere, the respiration is stertorous, the face is blue, the attack terminates with exhaustion of the nervous centres implicated. In these phenomena the medulla oblongata is principally concerned, and the therapeutic indication is plain; every medicament which tends to diminish the excitability of the medulla oblongata, and the cerebral anæmia which results from it, is applicable to the treatment of epilepsy. But before beginning the consideration of the physiological treatment of epilepsy, I will say a few words about the empirical treatment.

Certain simple herbs have enjoyed a great repute in the treatment of epilepsy, and the common people have accorded heroic curative virtues to a number of indigen-

ous plants which deserve a brief mention here, as their anti-epileptic properties have been endorsed by certain physicians.

Galium verum and *galium mollugo* ("white cheese rennet," "yellow ladies' bedstraw," are the familiar names) are reputed as having quite special virtues in the treatment of epilepsy, and we are frequently referred to the observations of Jourdan and Miergues, fils. I believe that even now certain religious communities in France treat this disease with the expressed juice or an infusion of this plant.

Valerian is also an ingredient of a great many anti-epileptic preparations, and its employment in this disease is supported by a respectable number of eminent names. I will pass rapidly by hyoscyamus, vaunted by Storck and Hufeland; daffodil, employed with success by Dufrenoy, Vieillechère, Delonchamps; bitter orange leaves, counselled by Larcher; peony, extolled by Portal, to devote a moment's consideration to belladonna, which, before the introduction into therapeutics of the bromides, was one of the medicaments the most depended on in the treatment of epilepsy, supported, as it was, by the authority and experience of Trousseau. Belladonna is given in the form of pills, each containing one-sixth of a grain of the powder and one-sixth of a grain of the extract; dose, one pill morning and evening the first month, and every succeeding month you increase the dose by one pill a day till you arrive at the enormous dose of twenty pills night and morning.

All these medicaments, belladonna included, are to-day completely abandoned; they have had to yield their place to more active and more certain medicines, and I have only mentioned them here because they belong to the history of the therapeutics of epilepsy. By the side of these vegetable substances we must place the mineral remedies which have been prescribed for the falling sickness; these are especially certain metals, such as silver, copper, and zinc.

What physiological action can these metallic substances have in the treatment of epilepsy? We cannot say; possibly we must invoke, in explanation, the strange phenomena of metallotherapy observed in accordance with Burq's method. However this may be, silver is administered in the form of pills of the nitrate, and in doses sufficiently large and sufficiently prolonged to produce discoloration of all the tissues. They tell a story of an aide-de-camp of King Louis Philippe, who had been cured of his epilepsy by this treatment, but whose skin was changed to a deep blue. I myself saw, twenty years ago, a man transformed into a negro (blue man they called him) by the internal usage of nitrate of silver, but who, notwithstanding this kind of poisoning, was not cured of his disease.

Copper is administered in the form of ammonio-sulphate of copper, and is given in the dose of ten centigrammes a day in capsules. Zinc is given in the form of oxide; Herpin is the most zealous advocate of treatment by this remedy. Out of thirty-six patients treated by oxide of zinc he obtained twenty-eight cures; the dose given was ten centigrammes three times a day, gradually increased till six grammes were taken in the twenty-four hours. Like the vegetable treatment above described, the metallic treatment of epilepsy has gone out of vogue, and to-day it is to the bromides that everyone has recourse.

When Balard, in 1826, discovered bromine, and the striking resemblances between this substance and iodine were pointed out, it was proposed to substitute the first medicament for the second, and it was in the treatment of syphilitic affections more especially that the substitution was made. From 1840 to 1850, in the Hôpital du Midi, the physicians attached to this hospital, and in particular Ricord, employed bromide of potassium in the place of iodide of potassium. The first labors recording the results of this treatment, and showing the physiological and therapeutical properties of the bromide were made

by two internes of the hospital, Rames of Aurillac and Huette, of Montargis. The thesis of Rames appeared April 25, 1850, and that of Huette several weeks after. Five years ago (in 1878) George Huette, in an excellent monograph on bromide of potassium, showed us the progress made in the usage of bromide of potassium since the first experimental and clinical studies of his father in 1850. Those early investigations, while clearly setting forth the physiological, therapeutical, and even toxic effects of the bromide, made no mention of any application of the drug to the treatment of the neuroses, and in particular to epilepsy.

The year following Locock, taking up a discovery, made several years before by a German, Otto Graf, who had noted in himself a marked depressant action following the use of large doses of bromide of potassium, and in particular, sedation of the genital functions, for the first time applied these data to the treatment of hystero-epilepsy and of epilepsy, and out of fifteen cases treated by the bromide recorded fourteen cures. The name of Locock ought to be immortalized in the history of medicine; he deserves the gratitude of the whole human race, because in consequence of his happy discovery of the use of bromide of potassium in epilepsy, he has enabled us to cure one-half our cases.

After the labors of Locock came those of Radcliffe, Brown-Séquard, and especially of Williams, showing that one could in five months diminish in a marked manner the number of attacks in a given number of epileptics. From this moment, bromide of potassium has been almost exclusively employed in the treatment of epilepsy, and the memoirs of Voisin, Legrand du Saulle, Falret of Lasigue, etc., in our country, show the beneficial results which may be expected.

Consult these documents, examine the statistics furnished by these physicians, and you will see that in more than half the cases we may favorably modify the condition of epileptic patients. I say modify, and not cure, for I range myself on the side of those who contend that a complete and permanent cure of real epilepsy by the bromide treatment is rare, without being, nevertheless exceptional. But it is possible, in one case out of every two, to cause the attacks to disappear, on condition always, of prolonging indefinitely the medication; and this is no small blessing. The bromide is, then (in the words of Legrand du Saulle), the muzzle of epilepsy, rather than a definite curative medicament.

How ought you to institute the bromide treatment? Which bromide ought you to choose? What are the inconveniences of this medicament? How long ought you to continue the treatment? These are questions which I must now answer.

But I must first of all say something about the physiological action of the bromides. Already, *apropos* of diseases of the heart, I referred to the action of bromide of potassium on the economy, and I need not repeat what I then said. All physiologists are to-day agreed in conceding to the bromide a sedative action on the cerebro-spinal axis, and in particular on the medulla oblongata. If any point is under dispute, it is not whether this substance has an elective action on the rachidian bulb, but whether this action is primitive or secondary. Some, as Germain Sée and Binz, maintain that the bromide acts first on the heart, and consecutively, by producing anemia, on the bulb; others, on the contrary, affirm that the heart is affected secondarily; that it is only influenced because the medulla oblongata has been first depressed. This depressant action on the excito-motor power of the mesocephalon is of marvellous applicability to epilepsy, since we have just seen that in this neurosis it is excitation of the rachidian bulb which determines the congeries of symptoms which characterize epilepsy, and this physiological action explains why suspension of the convulsive attacks follows the use of the bromide.

In the bromides what is the active principle? Is it

the bromide, or is it the base? This is a question which has been much studied, and which seems to us to-day to be solved. The bromide plays a considerable part in this depression of the bulbar functions, but the base does not by any means remain inactive or inert. And this it is which explains the difference of action of the different bromides. We know, especially since the labors of Laborde, that the salts of potash have a much more marked depressant action than the salts of soda, and that they have a toxic effect on the heart in particular. Already, when treating of purgatives, I showed you the difference which exists between the salts of potash and of soda; there is the same difference between chlorate of potash and chlorate of soda, as Laborde has shown; also between bromide of potassium and bromide of sodium, the first being more active than the second, while on the other hand the sodium salt is better tolerated than the potassium salt.

I have made many trials of bromide of sodium in epilepsy, and notwithstanding the considerable doses exhibited, 10 to 12 grammes (150 to 180 grains) a day, I have never succeeded in arresting attacks either of petit-mal or grand-mal by this salt. I have, therefore, been astonished to see in Hammond's remarkable work on "Nervous Diseases," that this eminent neuropathologist gives the preference to bromide of sodium in epilepsy.¹

By the side of bromide of potassium we must place bromide of ammonium, which has a still more powerful action than the first; then bromide of calcium, with which I have never experimented, but which is much employed in America, and especially by Hammond. The latter, while giving the preference to bromide of sodium, considers bromide of calcium superior to the potassium salt; one gramme producing a sleep which is calm and refreshing. His vehicle of administration of the calcium preparation is syrup of the lactophosphate of lime.

I have enumerated the alkaline bromides, of which the most employed is assuredly bromide of potassium. These bromides are often associated in prescription, a mode of administration called the *mixed bromides*.

There are other bromide compounds which are sometimes given, as the bromide of zinc and bromide of camphor. Theoretically, the zinc bromide should be a good preparation, since zinc oxide possesses anti-epileptic properties, as we have before seen. Bromide of zinc is used in England and America in the form of a syrup. Hammond speaks highly of this salt in epilepsy.²

Introduced into therapeutics by Deneffe, of Brussels, and investigated chemically by Clin, therapeutically by Bourneville, bromide of camphor has been employed in the treatment of hysteria and epilepsy, and although favorable results have been obtained at the Salpêtrière, yet this preparation has not come into general use. Thus far the bromide of potassium remains the medicament the most active and most employed in the treatment of epilepsy.

How shall bromide of potassium be administered? Although it has been attempted to introduce this salt by the hypodermic method and by enema, these tentatives have been promptly abandoned, and for the reason, as I told you when treating of diphtheria, that bromide of potassium has an irritant and even caustic action. We are then restricted to the alimentary canal as the only practical way of introduction, and when given it should be diluted with a considerable quantity of water; the dra-gees, granules, and compressed pills containing bromide should be discarded. I should add that when you are

forced to increase the dose of this salt, as in epilepsy generally, you should require the patient to partake freely of milk, in order to avoid the gastro-intestinal irritation which results from the prolonged use of the bromide in large doses.

The quantity of bromide which ought to be administered daily is very variable. From twelve to fifteen grammes a day have been given; the medium dose, in the majority of cases, is eight grammes. This dose cannot be given from the first; you must begin with smaller doses, as one gramme morning and evening, and gradually increase the dose till you have obtained complete control of the disease. Voisin thinks that we should regard as the maximum dose that which determines abolition of the reflex sensibility of the pharynx. I believe that this is an excellent rule in the case of hysteria, but not in epilepsy, and that in this disease we must not only attain abolition of pharyngeal reflex irritability, but we must, if occasion demand, push the administration of the remedy even farther, till we have stopped the attacks. But it is absolutely necessary to have a bromide preparation which is chemically pure, for Voisin has shown that the impurities of this salt considerably modify the therapeutical effects which it produces.³

These large doses of bromide, given for therapeutic effect, are not without danger. They determine in certain patients a train of symptoms which in some instances have been grave enough to cause death, and to which the name *bromism* has been given. Besides the inconveniences mentioned in my lecture on hysteria, and which are the acne eruption, the disagreeable odor of the breath, the peculiar unpleasant taste of the saliva, there are certain nervous manifestations of a grave kind, such as I lately observed in one of my patients who had taken in one day thirty grammes (a troyounce) of bromide of potassium. These symptoms consisted in a remarkable depression of the vital forces. The patient could not stand, could not make the least movement without difficulty. Intelligence was impaired, and there was aphasia and amnesia.

This state, in which the patient is plunged into a physical and moral brutishness the most deplorable, persists till elimination of the bromide by the various excretories has taken place.

These inconveniences of the bromide treatment are again and again experienced by the epileptic patient, who finds himself often in a sad dilemma; either he must desist from the use of the remedy and see his fits come back, or persevere in the treatment, notwithstanding the depression of all his faculties and forces. Believe me, he will generally choose the latter as the lesser evil, rather than suffer those terrible attacks which are to the epileptic a menace always suspended over his head.

But it is especially in the delirium of action, which makes the epileptic a criminal without his knowing it, that it is necessary to employ the bromide in massive doses in order to overcome the mania which impels him, unconsciously, to deeds of violence. Nothing, in fact, is more curious than to see in the wards of our lunatic asylums men enjoying their intelligence and their reason who have committed, and would still commit, the most astounding murders, if their maniacal propensities were not kept in check day by day by immense doses of bromide.

How long should you continue the bromide treatment of epilepsy? Often a very long time, and even during the

¹ Hammond on Nervous Diseases, p. 806. Paris, 1879.

² W. A. Hammond: The Therapeutic Usage of Calcium Bromide, New York Med. Jour., 1872, and Bull. gen. de Therapeutique, 1872; also, Hammond on Diseases of the Nervous System, p. 886. Hammond's formula for bromide of zinc is as follows:

R. Bromide zinc, ... grammes iij. (or gr. xlv)
Syrup simplicis, ... grammes xxx. (1 fl. oz.)

M. Dose.—Ten drops three times a day. The quantity to be gradually increased till thirty drops or more are given at a time. Each dose should be well diluted with water before taking, as it is apt to offend the stomach.

³ The purity of the bromide salt is a point of capital importance. It ought especially to be free from the iodide. To determine the presence of iodide of potassium, dissolve the suspected salt in starch water, add a few drops of nitric acid, and if there be any iodide of potassium present you will obtain a blue color from the formation of iodide of amyl. Lambert's method is even more delicate. Dissolve the bromide in a solution of potassium permanganate; if the bromide is pure the solution keeps its violet color, while it takes a yellowish tint if there are any traces of iodine present. According to Lambert a chemically pure solution of potassium bromide when treated by HCl, should evolve a few bubbles of CO₂. Treated by one gramme of benzene, and a few drops of bromine water, it ought not to give a rose color. Treated by HNO₃ and nitrate of baryta, it ought not to turn yellow (Adrien: Researches on the Chemical Composition of Preparations of Bromide of Potassium, Bull. gen. de Ther., t. lxviii., 1870; Lambert: How to Detect the Presence of KI in Bromide of Potassium, Bull. gen. de Ther., t. lxii., p. 593, 1867).

entire life of the patient. When, moreover, you have obtained the full benefit of the drug, and have witnessed complete cessation of the attacks, you must not leave off abruptly the medicine, but must keep on with it for several years, gradually diminishing the dose, as Legrand du Saulle has advised.¹

Under the influence of bromide medication, thus carried out, we witness mitigation, diminution in frequency, then disappearance—first of nocturnal then of diurnal attacks; then the vertiginous paroxysms and the aura cease, symptoms which most resist the bromide treatment. These favorable results you will, as I said, obtain in one-half your cases. But you can often anticipate what will be the result of the bromide treatment by determining the cause of the epilepsy. Here Voisin has given us valuable hints. The epilepsy which results from malformations of the cranium or cerebral tumors is rebellious to the bromide, while the functional and hereditary neurosis is amenable to this treatment. Sex has no influence one way or the other.

Such, gentlemen, are the leading indications and methods of the bromide medication in epilepsy. If not absolutely and certainly curative, this medication, nevertheless, represents a real therapeutic progress when we consider the unsatisfactory nature of the treatment of olden times. I ought to add, as an item of interest in this connection, that experimental physiology has confirmed ordinary clinical results; I allude to the recent curious experiments of Albertoni, who, after prolonged administration of the bromide to animals was not able to induce in them experimental epilepsy by irritating the cerebral cortex, although after giving atropine under like circumstances such convulsive attacks could easily be provoked.²

Other remedies which act on the medulla oblongata, or on the muscular system, have been prescribed in epilepsy, such as picrotoxine, bromide of gold, curare, and nitrite of sodium.

Curare or wourari has been tried hypodermically in epilepsy by Voisin and Liouville; the effects are not sufficiently encouraging to warrant continued use of this medicament, notwithstanding the more recent trials of Edlefsen and Kunze. Picrotoxine, the active principle of *cocculus indicus*, has been made the subject of study by Brown-Séquard, Glover, Bonnefin, Vulpian, and others. These researches show that picrotoxine has an elective action on the medulla oblongata, and may even determine a veritable experimental epilepsy. Planat has utilized this special selective action of picrotoxine in the treatment of epilepsy; I have myself experimented with it, but have not obtained favorable results except in alcoholic epilepsy—which will get well of itself if the patient will practise abstinence from alcohol. Vulpian has also tried it without any success. Add that picrotoxine is very poisonous, even in small doses, and we ought to conclude that this medicament should have a very humble place in the treatment of epilepsy.

Finally, Huchard has recently advised the association of digitalis with bromide in the treatment of epilepsy, and claims good results from the combination.

Thus far we have been occupied only with the general, or pharmaceutical treatment of epilepsy; it remains to speak of the hygienic treatment, and of that of the attacks.

If hygiene has not a preponderant part in the treatment of epilepsy, nevertheless it is not without influence

on the production of the attacks. Here, as in hysteria, the question of marriage comes up for consideration. Ought an epileptic to marry? It is well to bear in mind, and to urge upon your clients, when they consult you in reference to the marriage of an epileptic, that epilepsy, with all its gravity, is not necessarily and fatally hereditary, and in giving this opinion you can fortify yourself by the authority of professor Laségue, than whom no one is more qualified to judge on questions of this kind. In fact, Laségue denies the hereditary nature of epilepsy. This is a matter of considerable importance, and holding this view we are enabled to tone down somewhat the sombre colors in which such a union would otherwise be invested.

If continence does not play an important part, it is not the same with venereal excesses, which have a most decided influence in the production of attacks. Masturbation is most pernicious to epileptics, and destroys, in a certain measure, the effect of the treatment by bromides.

Epileptics should live in the country and avoid crowded assemblies, political gatherings, concerts, shows, and the like. You must often have remarked that theatrical exhibitions are frequently interrupted by attacks of epilepsy, and this for the reason, principally, that the bad air and the heat of the apartments are deleterious to epileptics.

The alimentary regimen has a certain influence on the falling sickness. First of all, the alcohols are themselves a cause of epilepsy, and you are not ignorant of the studies of Magnan as to alcoholic epilepsy, and in particular that form of epilepsy which is produced by absinthe; it is proved that these nerve-excitants produce epilepsy in men and animals; you ought then to interdict the use of alcoholic beverages to your patients.

You ought also to advise a diet which shall contain nitrogenous substances in very sparing quantity. It seems, in fact, proven that a vegetable diet diminishes in a marked manner the number of attacks, while an azotized diet considerably increases them; the epileptic, then, should be strictly vegetarian. To sum up the rules of hygiene, the epileptic patient should live much in the open air, be very moderate in sexual indulgences, take a great deal of exercise, abstain from spirituous liquors, and live almost exclusively on vegetable food.

As for the treatment of the attack, it consists in placing the patient in a horizontal position, and loosening any part of his apparel which may cause constriction of the neck or thorax. It is generally customary to place some hard substance (as a clothes-pin) in the mouth of the patient to prevent biting of the tongue, a means which has not been very successful; the foreign body, if too resisting, breaks the teeth of the patient, and if too little resisting, is liable to be bitten off in the struggle, and to find its way to the throat or windpipe of the patient, causing suffocation.

Certain measures have been advised to prevent the convulsive seizures, such as the energetic flexion of the great toe, compression of the temporal regions, of the infra-occipital hollow, etc. Others have counselled by various compressions to prevent the aura from spreading; Rozier has even devised a special instrument for this purpose. All these means are only of use in certain exceptional cases where the epileptic has premonition of his attack by sensations of aura which precede the convulsive seizure by a brief interval. It has also been proposed to employ during the paroxysm, hypodermic injections of apomorphia, inhalations of bromide of ethyl, and nitrite of amyl. Bourneville has given us some interesting facts relating to the two last medicaments, but these inhalations have not come into general use.³

¹ His rules are as follows: We will suppose a case apparently cured. During the first year—fifteen days of each month with the bromide every day in the usual dose, and fifteen days with the bromide every other day. In the second year—fifteen days of every month with the bromide every third day, and fifteen days with the bromide every day. In the third year—fifteen days of every month with the bromide every day, and fifteen days with the bromide every fourth day. In other cases (and this is now his habitual method), after the patient has gone one year without an attack, bromide treatment six days in the week. After fifteen months of freedom from attacks, bromide five days in the week. After eighteen months, bromide four days in the week. At the end of two years from the last attack bromide only three days in the week (*Traitement et Curabilité de l'Epilepsie*, by Legrand du Saulle).

Méd. de Lyon*, t. xvi., pp. 500-502, 1864; Du-jardin-Beaumez: *Art. Absinthe*, in *Diet. de Ther.*, 1882; John Mersin: *Influence of Food and Hygiene in Epilepsy*, *West Riding Lunatic Asylum Med. Reports*, 1875; Bourneville et Ollier: *Recherches sur l'Action physiologique du Bromure d'Ethyle dans l'Hystérie et l'Epilepsie*, *Gazette Méd. de Paris*, No. 35, 1880; Bourneville: *Du Nitrite d'Amyle dans l'Epilepsie*, *Soc. de Biol.*, *Janv.*, 1875.

This finishes what I deemed important to say relative to the treatment of epilepsy, and the beneficial influence of therapeutics in this terrible disease. In the next lecture I shall consider chorea and its treatment.

Progress of Medical Science.

IRREGULAR WORK WORSE THAN OVERWORK.—At the present time, when we hear so much of the evil consequences of what is rather loosely termed "overwork," the following remarks of the *British Medical Journal*, July 14, 1883, seem quite *apropos*: "'Overwork,' properly so called, is not so likely to occur, or if it occur to do mischief, as irregular or disorderly activity. If there be not sufficient time for recuperation in the course of work, exhaustion must take place. If the work done be of such a nature as to put an undue strain on any one faculty, harm may be done, although the brain as a whole may not be severely taxed. If the supply of brain-food be insufficient to enable the recuperative faculty to compensate by food for consumption in use, there must be exhaustion. If work be exacted when any indication of exhaustion is present, it is impossible that injury shall not be inflicted. It follows that educators have especial need of care to avoid engaging the brains of their pupils in work for more than very short periods, and to provide intervals during which there may be rest of the centres specially taxed. Much may be done by changing the kind of work frequently. We are of opinion that no growing child should be kept longer than half or at most three-quarters of an hour at one task, or even the same description of work. Again, the great centres of relation should not be overtaxed. Vision, hearing, the speech centre, and the centre specially concerned with written language, whether in writing or reading, should not be wearied. Brain weariness is the first indication of exhaustion. The faculty of 'attention' is perhaps one of the most easily vulnerable of all the parts or properties of brain-function. It is the faculty which most readily becomes permanently enfeebled, and when weakened entails most trouble in adult life. In children it is difficult to catch and fix the attention. No effort should be spared to secure this fixity of thought; but in order to avoid weakening the power of 'thinking'—as distinguished from 'thought-drifting'—the teacher should not strive, or desire, to hold the attention by any effort on *his* part longer than it is voluntarily given by the child. The slightest indication of exhaustion should at once be met by a change of task. If these hints, general as they are, can be reduced to practice, we think there is little fear of 'overwork' or harm from brain activity. Desultory and insufficient work is more to be feared by far than 'overwork,' because the brain, like every other part of the organism, grows as it feeds, and it can only feed as it works."

A RENAL FORM OF TYPHOID FEVER.—Dr. Didion has chosen this subject for an inaugural dissertation, and comes to the following conclusions. Typhoid fever produces a renal congestion, which plays an important part in the course of the disease. Albuminuria is almost constant, but generally slight and temporary; when abundant, it is a sign of true nephritis. The real inflammation is both parenchymatous and interstitial, and produces certain characteristic symptoms, such as asthenia, stupor, dryness of tongue, cedema of the face and legs, lumbar pains, cutaneous eruptions (pemphigus, ecthyma, boils), and an alteration in the urine, which has a reddish color and the odor of boiled bread; in the deposit, red and white blood-corpuscles are found, as well as casts; the urine contains a large quantity of albumen. The diagnosis can easily be arrived at by the above-mentioned symptoms. The termination is often fatal, either from asthenia or uræmia.

As to the treatment, Bouchard recommends carbolic acid and the salicylates, Polli the sulphites, Klebs the benzoate of potash. Leeches, mustard poultices, and cupping in the lumbar region are useful; but blisters, even with the addition of camphor, must be avoided. In certain cases, the disappearance of the symptoms is accompanied by abundant diuresis, which ought, therefore, to be favored if possible; but all diuretics are not equally good, those which possess irritating properties must be avoided. The best in these cases is milk, pure or mixed with water. Whatever may be the way in which it acts on the kidneys, it is always well borne, and its action is double; it increases the secretion of urine, and hastens the elimination of toxic principles, without producing any irritation, even in the most acutely inflamed kidney. Subcutaneous injection of pilocarpine might perhaps be useful; in one case, when the skin was dry and burning hot. Dr. Didion injected twice daily one-sixth of a grain of pilocarpine, and under its influence the skin became moist and abundant sweat was produced; the tongue also was less dry than before; the temperature fell in two days from 105.8° to 98.6° F.; but three days later the patient died, after the temperature had once again reached 104° F. New investigations are necessary before we can arrive at definite conclusions. As for the cold baths, Gubler thinks that they are contra-indicated in case of nephritis, but Libermann considers their use as surely beneficial in spite of it. Several patients who had been subjected to that treatment did not complain of any inconvenience, and cold lotions rapidly applied to the trunk and limbs with a sponge seem to relieve the patient, lower the temperature, and re-establish the functions of the skin. All these advantages must be weighed against the danger of a renal congestion; but further experience alone can show which treatment is most advantageous.—*British Medical Journal*, July 14, 1883.

ALBUMINURIA FOLLOWING CUTANEOUS IRRITATION.—Dr. Mihran has investigated this subject, and formulates the following propositions: 1. Cutaneous excitement, by whatever means produced, may give rise to albuminuria. 2. The amount of albumen, which, in such a case, can be almost at once detected, will vary according to the degree of excitement, the energy of the exciting agent, the extent of surface acted on, and the duration of the excitement. 3. The duration of the albuminuria will also be determined by the same conditions; in most cases it is transient, but, under the influence of extreme peripheral irritation, it may persist, along with an alteration in the organic structure involved. 4. Albuminuria proceeding from cutaneous excitement depends proximately on a disturbance of vaso-motor innervation.—*Journ. Cut. and Vener. Dis.*, July, 1883.

A NEW METHOD OF APPLYING PRESSURE TO ENLARGED TESTICLES.—In the *Lancet* for July 7, 1883, Dr. Corbett describes a simple method of applying pressure to enlarged testicles, which is calculated to do away with many of the objections against the ordinary plaster strapping. He prefaces the explanation of his plan by saying that he derived the idea from a homely source, nothing more or less than seeing the means employed for encasing a football; barring that, instead of having the encasing material made of leather, he had it made of india-rubber—such as one sees in the construction of the balls in spray producers, etc. The cases he recommends should be made of different sizes and thicknesses, and oval in shape. The means of tightening the cases and applying the pressure would be identically the same as in the football cover—*i.e.*, by lacing. There should be an opening at the neck of the case to allow the passage of the cord. This opening would be surrounded by a ring (interrupted) of leaden wire, to ensure its patency and to prevent pressure on the structures of the cord. The leaden wire ring being interrupted, its softness would offer no obstacle to its easy adjustment round the neck of

the enlarged gland. With a supply of such cases, the treatment of an enlarged testicle would offer but little difficulty. It would simply mean the selection of a rubber case of the right size and thickness, and capable when laced up of exercising a steady equable pressure on the enlarged organs, and applying the case to the testicle and lacing it up. If considered necessary, the testicle could first be enveloped in a thin layer of cotton-wool. This would prevent any possibility of the skin being nipped or chafed by the lacing. As the gland reduces in size a smaller case would be applied, and thus a steady pressure kept up until a cure was effected. The above plan has the advantages of simplicity, neatness, and quickness in its application to recommend it. It involves no elaborate apparatus, and does away with many, if not all, of the objections connected with the operation of strapping with plaster.

A CASE OF TRACHEOCELE.—A merchant, twenty-nine years of age, of previous good health except for an attack of rheumatism, acquired a bronchitis with severe cough. After a severe attack of coughing he suddenly noticed a small tumor, the size of a hazel nut, just above the sternum. In three days this had increased to the size of a pigeon's egg, and incommoded respiration and deglutition. The tumor remained stationary for three weeks, when it suddenly opened and discharged blood and pus, and became much reduced in size. It grew again slowly for a time, but remained smaller and softer than before. It was larger during expiration and diminished again in size during inspiration. Upon compression a fine crepitation could be felt, and the tumor disappeared. The treatment consisted in permanent compression of the hernia by a sort of truss, and resulted in a cure after the expiration of six weeks. The patient, however, became the victim of chronic asthma, from which relief could only be obtained by constantly increasing doses of morphine. From a study of this case, and twelve others, reported by different observers, Dr. Déti's arrives at the following conclusions: 1, the causes of the affection are bodily exertions of any sort; 2, the principal symptoms are enlargement of the tumor during expiration, disappearance of the same under compression, and a muffled, squeaking voice; 3, the prognosis is favorable; 4, treatment is purely local and consists in steadily maintained compression.—*Centralbl. für Chirurgie*, July 7, 1883.

BATHERS' CRAMP.—Some recent bathing fatalities have again drawn attention to the important subject of bathers' cramp. If the nature and causes of this dangerous affection were more generally known, it is probable that many deaths from drowning in the bathing season might be prevented. Cramp is a painful and tonic muscular spasm. It may occur in any part of the body, but it is especially apt to occur in the lower extremities, and, in its milder forms, it is limited to a single muscle. Pain is severe, and the contracted muscles are hard and exquisitely tender. In a few minutes the spasm and pain cease, leaving a local sensation of fatigue and soreness. When cramp affects only one extremity, no swimmer or bather, endowed with average presence of mind, need drown; but when cramp seizes the whole of the voluntary muscular system, as it probably does in the worst cases, nothing, in the absence of prompt and efficient extraneous assistance, can save the individual from drowning. Although the intimate nature of muscular cramps, and the precise mode in which they are established, are still unknown, experience has furnished us with sufficient data on the subject to enable us to recognize the chief conditions of their causation. These conditions are: a peculiar individual susceptibility or idiosyncrasy; the shock of cold applied to the general surface of the body; prolonged muscular exertion; and forcible and sudden muscular exertion, especially in the direction of the extension of the extremities. There can be no doubt about a liability to muscular cramp being

an individual peculiarity. The disorder is especially apt to arise in persons of irritable temperament. While cramp has been met with in all ages, sexes, temperaments, and climates, it has been observed that it occurs far more frequently in warm climates than in cold, and chiefly in the hottest of warm climates, and that persons of middle age suffer most from the affection, and men more so than women, and the robust and vigorous more so than the weakly. Neither can there be any doubt that the shock of cold applied to the surface of the body, especially when the body is unduly heated, is the commonest determining cause of the worst and most extensive forms of bathers' cramp. On this fact is founded the common prejudice against bathing when the body is much heated. Many fatal cases have illustrated this point. Only a short time ago, a robust soldier, who was an expert swimmer, rowed in a boat, upon a sultry evening, to a deep pool; here, with his body glowing from muscular exertion, he plunged into the water with the intention of taking a refreshing bath, when he was immediately seized with general muscular cramp, so that the poor fellow was at once drowned. That mere prolongation of muscular exertion, as in continued swimming, and forcible and sudden muscular exertion, particularly in the extension of the extremities, as in swimming with very vigorous and rapid strokes, are, respectively, efficient and frequent determining causes of cramp, familiar experiences to every swimmer. These muscular conditions, however, usually give rise only to the slighter and more localized forms of cramp. Serious cramp is a peril which menaces most persons with highly developed muscles. Its most powerful and most avoidable cause is the sudden immersion of the body, when its surface is highly heated, in water of a relatively low temperature.—*British Medical Journal*, July 14, 1883.

THE ABSORPTION OF WATERY SOLUTIONS BY THE SKIN.—From an examination of this subject (*Ann. de Dermatol. et de Syph.*), Dr. Aubert concludes the following: 1. Substances dissolved in water may make their way through the epidermis without producing any visible external lesion. 2. Nevertheless, the essential condition of such penetration appears to be a break in the epidermis where it is prolonged into hair-sheaths, and along the included portions of the hairs themselves. 3. In fact, according to our observations, this penetration takes place exclusively in hairy parts. 4. It is promoted by whatever causes the hair to be pulled about, as, for instance, friction with the moist or dry hand, or unusual size, stiffness, and length of the hairs. 5. A delicate integument and thin cuticle afford unfavorable conditions, on account of the less vigorous growth of hair on parts thus endowed. Total absence of hair is likewise a condition eminently unfavorable to absorption. 6. Hence we may infer the possibility of introducing soluble substances into the circulation by causing them to penetrate the epidermis in small quantities, either with or without the aid of baths. To effect this, friction with the palm of the hand would have to be applied forcibly over a large surface, and especially where the skin is hairy. The only possible unpleasant effects would be a moderate degree of inflammation, manifested in a little redness and smarting about the roots of the hairs. 7. Simple immersion in a bath, however prolonged, could not be relied on to effect the entrance of even the smallest quantity of a solution through the skin.

RECTAL EXAMINATION FOR VESICAL CALCULUS.—Professor Volkmann states that after the patient is completely anesthetized one hand should be placed over the pubis, introducing the forefinger of the unoccupied hand into the rectum. In this manner it is easy to grasp a stone with the upper hand, especially in lean subjects. Sometimes it is possible to pass a ligature around the abdominal walls inclosing the stone. In vesical papillomata and myxomata with long pedicles, this ligation might be of use.—*Archiv für Chirurgie*.

THE HYGIENE OF DOG DAYS.

THE oppressive heat of this season is alluded to by Virgil, who ascribes to the baneful influence of Sirius corporal languishment and disease.¹

How to keep strong and well when the thermometer is 90° in the shade and there is not a breeze, and the atmosphere is full of moisture; when the appetite flags and digestion languishes, and toil is irksome, is the perplexing question.

By common consent for the inhabitants of cities, for all men of business and all professional men, this is the holiday season, and nothing in the economy of nature is more appropriate than that citizens should fly to mountainous regions of the country, or the seaside for coolness, invigorating air, rest, and recreation during this trying period, when the air of our crowded cities is rank with decomposition and corruption.

Not to dwell on the peril to the cerebro-spinal system of excessive heat; and it is a matter of frequent observation that exhaustion of nervous energy, phlegmasias and even death are thereby produced—not to dwell on the relaxation of the muscular system, of the perspiratory system, and the venous congestions which all experience to a greater or less degree, the digestive organs are undoubtedly the most exposed to danger. Over-eating, and the eating of improper food are sins of dog days as of all other periods. A considerable portion of the human race have not self-control when impelled by appetite, and never learn self-control by the dearest bought experience. Green fruits and green vegetables are in the market. There is little desire for ordinary food, but these new products of the soil, though generally immature, are palatable and appetizing. The weakened stomach is oppressed by a burden which it cannot digest, and *embarras gastrique*, enteritis, or cholera morbus results. Happy the summer gourmand if, warned by a diarrhoea, he practises abstinence in time to escape worse evils.

So patent is it to every physician that a large part of the physical ailments of dog days are due to indulgence in green fruit and vegetables, that all citizens—those that stay at home to swelter during the hot weather, and those

that frequent the watering-places—cannot be too much cautioned as to the danger of much indulgence in the good things with which their tables, at this season of the year, are loaded. If, as at a medical banquet we once attended, the green corn could be labelled *cholera* the green peas *colic*, and the lobster salad, *despair of a jaded stomach*, only the simple truth would be told, however much it might seem like a stupendous joke. If the appetite be poor, the powers of the stomach are enfeebled, and should not be taxed. Food of an easily digestible character should be eaten, such as stale bread, oatmeal, pure milk (if obtainable), rice, a little fresh fish or *tenderloin*, broiled, not fried, chicken-, veal-, or mutton-tea, with a little soda biscuit, cooked ripe fruits in moderation. Heavy boiled dinners (fit only for the “tough stomachs of reapers”); rich puddings and pastries, salads, green legumes, fried meats, and animal food generally, should be either not indulged in at all, or eaten very sparingly.

Frequent ablutions form an important part of the hygiene of warm weather. The whole body should be bathed with lukewarm water twice daily, and if there be sufficient constitutional vigor to stand a cold bath, this will prove very invigorating.

Will it do to take a cold plunge while perspiring? This question has been answered both negatively and affirmatively. The common impression has been that a bath taken during active perspiration is likely to be injurious; therefore a hygienic rule has been established forbidding cold bathing at such times. This is a rule, however, which is transgressed by laboring men and farmers with impunity, and it is well known that in the European hydrotherapie establishments it is advised as preparative for the cold douche that the patient should take vigorous muscular exercise before the douche, in order to induce sweating; and it is at the period of greatest muscular activity that the cold plunge or douche is taken. It is maintained that the greater the difference between the temperature of the body before the douche and that of the water the more active the reaction will be. It is perhaps safer to follow the traditional opinion; at all events, the cold douche should be short. There is no question that the free external use of cold water is a powerful promoter of tone, and that many a vigorous literary man and accountant owes his robustness during the summer months to regular habits of cold bathing. Sea bathing is especially recommended to those who are in a situation to enjoy this incomparable hygienic luxury.

The air in dwelling-houses should be made as wholesome as possible, and all ill-smelling nuisances in the vicinity should be speedily abolished. Foul smells may not contain disease-germs, but they certainly offend the respiratory and digestive organs. The windows of sleeping apartments should be kept constantly open.

The daily tasks should be lightened in correspondence with the diminished capacity for hard work; opportunities for recreation should be improved, and sleep should be abundant. An hour of sleep after dinner is invaluable to most hard working men.

Such are some of the hygienic rules applicable to dog days; they will perhaps be less heeded by busy physicians at watering places, to whom, as to farmers, this is a harvest season, than by intelligent citizens generally.

¹ Æneid iii., 141:

Sinquebat, dulcis animas, aut ægra trahebant
Corpora: tunc sterilis exurere Sirius ægros.

Also x., 274:

Ille Siti morbos que fereos mortalibus ægris.

CONCERNING THE VALUE OF EXAMINATIONS.

THOSE who read the very interesting paper by Surgeon Shufeldt in the present issue will be impressed with the truth of much that he says regarding the real value of examinations as tests of knowledge actually possessed. These examinations are, as Huxley very truly remarks, the necessary evils of our existing system of education. But that they utterly fail in very many instances of accomplishing their real purpose goes without the saying. The failure to pass is often due to absolute ignorance on the part of the candidate. When there is no question on this point the examination serves its real purpose. Too often, however, the trouble is with an examining board which adopts too arbitrary a standard, or imposes too exacting conditions. There is great need of drawing the dividing line somewhere between these extremes.

It has often been said with much truth that the prize men in college do not, as a rule, make much of a show in after-life. They belong to a class now becoming quite numerous, who study to pass an examination rather than to gain knowledge. "They do pass, and they don't know." On the other hand, the scholar at the foot of his class, who scrapes through by so-called blind luck, often surprises every one by his ultimate successes. But ordinary examiners never appear to dream of such possibilities, nor are any practical efforts made to ascertain the real extent of that groundwork of knowledge upon which future success in any calling must depend. An approach is made in that direction in the searching character of the Army and Navy examinations, but that is all. It may, and doubtless does, serve to keep out incompetent men, but it cannot always bring to the front and develop those whose best work is ahead of them. That examining board would certainly be a wise one which could, under all circumstances, be able to separate the chaff from the wheat. But while this may be considered impossible it must nevertheless be acknowledged that there is great room for reform regarding the accepted method of examination even in the Army and Navy. There should certainly be an attempt to approach a more practical standard, an endeavor to bring out the qualifications which shall best meet the real requirements of everyday life in camp, on the field, or in hospital. At present there appears to be more danger of shutting out many good men who would be destined to ornament the corps than of admitting ignoramuses who would be liable to be dropped at their second examination.

The second examination is right enough in its place, but its real aim should be to measure the qualification of the candidate according to the bent of his future usefulness to the service. Proficiency in one line of study should offset a lack of it in another. Thus each one could be placed properly to bring out his best talents and be encouraged to pursue a line of study before and after his second examination best suited to his taste and capabilities.

Even Surgeon Bill himself, if subjected to an examination to-day, might pass better in chemistry than either in anatomy or surgery. And yet it would have been quite a mistake to have rejected him on that account. On the other hand, we have not heard that the late Geo. A. Otis, whose masterly "Surgical History of the War of the Rebellion" is a monument of talent and industry, was much of a chemist.

News of the Week.

THE PROGRESS OF YELLOW FEVER.—The appearance of yellow fever among the marines at the Navy Yard, near Pensacola, has given rise to much speculation as to the manner in which the disease found entrance. Nothing definite has yet been ascertained, as those in authority are not disposed to stop to inquire *how it got there* until they have perfected their sanitary arrangements for preventing its spread. At the present writing seven cases are reported to have occurred among them by Dr. Owen, the medical officer in charge. Outside the reservation great activity has been manifested by the health authorities of Pensacola, supplemented by the Marine Hospital Service; immediate steps were taken to quarantine the reservation by land and water by placing a sanitary cordon around the infected camp, thus cutting off all personal communication between the reservation and the outside world. With an efficient quarantine and other sanitary measures it is believed the disease will be confined within its narrow limits. Last week two cases of fever of a suspicious nature, with one death, were reported from Ocean Springs, Miss., a point nearly opposite the Ship Island Quarantine Station. The house in which they occurred was at once disinfected and isolated by a sanitary cordon, and up to the present writing no further appearance of the disease has been reported. Dr. Austin, of New Orleans, regards the cases as very suspicious, but will decide against their being yellow fever if the disease does not spread—a thing not likely to occur if properly guarded by those in charge of the sanitary cordon, etc.

Considerable opposition to the location of the Cape Charles quarantine station, at Fisherman's Island, is still manifested by the Baltimore pilots, notwithstanding the fact that it is more convenient for them than for the Virginia pilots, who have offered no objection whatever, but on the contrary have aided the quarantine officers from the first in bringing foreign ships to anchor opposite the station. A few days since the Governor of Maryland issued an order instructing the Baltimore pilots in this matter, so that their opposition is confined to newspaper attacks instead of overt acts of insubordination as formerly. The station is now in good running order, and all foreign vessels are inspected before being allowed to proceed up the bay. Everything is satisfactory at the other United States quarantine stations: the one at Sapelo, on the coast of Georgia, designed as a place of refuge for infected vessels bound for any port between Charleston, S. C., and St. Augustine, Fla., has as yet had nothing to do.

Consular reports continue to indicate no increase in the fever at foreign ports. At Cardenas, Cuba, but four or five cases, and no deaths, are reported in the town for the week ending August 11th, and "no yellow fever among the shipping." At Matanzas there were four cases and two deaths in the city; none reported in the shipping. Previous reports of yellow fever at Colon (Aspinwall) have been contradicted by the Consul at that place. At Vera Cruz the disease continues in great violence. A cable despatch of the 13th instant states that the steamer Alexandria cleared for New York on

the 11th, and a second despatch, dated the 14th, that the steamer *Bernard Hill* cleared on that day for Baltimore. A third despatch, dated the 20th, announces the departure, on the 17th, from Vera Cruz of the steamer *City of Washington* for New York. These steamers will of course be carefully inspected, and quarantined if necessary.

Immediately upon the appearance of yellow fever at Pensacola Navy Yard a large supply of disinfectants and a half-dozen hospital tents were ordered by Surgeon-General Hamilton from the supply on hand at New Orleans. An additional number of tents were asked for by the Pensacola Board of Health, and twenty more sent them on the 21st instant. In order to insure safety a house-to-house inspection of Pensacola was ordered and commenced on the 21st instant. The following despatches from Pensacola and Fortress Monroe to Surgeon-General John B. Hamilton give the latest yellow fever news up to the hour of going to press :

PENSACOLA, FLA., August 20th.—No new cases at the Yard to-day. Pensacola perfectly healthy. Will commence inspection to-morrow. Will give you progress every day. Cordon perfect and under my personal supervision. Has performed good service already ; arrested thirteen persons. Cordon seventeen miles long, well protected by swamp and water, and all possible landings guarded. JOHN B. GUTTMAN, President Board of Health.

PENSACOLA, August 20th.—Board of Health request that I ask you to send twenty hospital tents. Reported eight cases and three deaths. J. M. TARBLE, Collector.

PENSACOLA, August 20th.—No new cases at Navy Yard for last forty-eight hours. Eight cases and three deaths reported to date. Villages of Warrenton and Woolsey perfectly healthy. Fever confined to Yard hospital. Surgeon Owen in critical condition. WHITE, Attending Assistant-Surgeon.

FORTRESS MONROE, August 20th.—Spanish steamer *Navarra*, from Havana and Cienfuegos to Baltimore, in ballast, etc., ordered in quarantine to-day. One suspicious case of fever, rest well. Will detain her several days for developments. HENRY SMITH, Surgeon.

The following brief history of the Norwegian bark *Salome*, is furnished by Surgeon Henry Smith, of the Marine Hospital Service, in charge of Cape Charles quarantine station : "Norwegian bark *Salome*, spoken by the Revenue steamer *Ewing*, off the Capes, August 15th, directed to remain at her anchorage in Lyme Haven Roads until boarded and inspected by United States quarantine surgeon. Was inspected at 6.30 A.M., the 16th, and ordered to quarantine station for observation, disinfection, and fumigation, and to allow no communication whatever until further orders. This vessel left Cardiff, Wales, February 6, 1883, for Vera Cruz, Mexico, with a cargo of patent fuel, arriving there April 25th, with a crew consisting of eleven persons, all on board well. The health of the men remained good until the cargo was discharged, when, on June 10th, ordinary seaman Soren Aslagnsen was taken down with yellow fever and died in three days of black vomit. The captain had the fever June 16th, but recovered, and the *entire ship's crew* were taken down in rapid succession. After ob-

taining ballast, the *Salome* sailed from Vera Cruz, June 26th, for Galveston, Texas, intending to take on a cargo of cotton-seed cake and oil ; was not allowed by the authorities to go beyond the inner quarantine, and ordered to the outer quarantine the next day. She arrived at the Galveston quarantine, July 1st, and the day following M. E. Nielsen, first mate, and brother of the captain, was taken with the fever and died July 4th. A passenger named Guerre, a Frenchman, and of New York, who took passage at Vera Cruz, was attacked July 2d (the same day as the mate), and died July 4th. The last death was that of Ole Tobiasen, a seaman, who was taken sick July 8th, and died July 14th, the day after sailing from Galveston, of black vomit, and was buried in the Gulf of Mexico—making a total of four deaths.

. . . An additional unacclimated seaman was shipped at Galveston two days before putting to sea ; all were found comparatively well upon arrival of the vessel at the Capes—thirty-one days having elapsed since the last death or case of any kind, the last man shipped having thus far escaped. She was disinfected and fumigated at Galveston. The *Salome*, which has caused so much anxiety because of her disastrous experience, I believe enjoys the distinction of being the first infected vessel to arrive with yellow fever at our shores in the present year."

THE PROGRESS OF CHOLERA.—But little if any progress has been made in the march of cholera during the past week, and the precautionary measures adopted by various countries, give hope that it may be kept at bay for another year.

A letter to the State Department from the Consul-General of the United States at Lisbon, Portugal, dated July 20, 1883, says : "Certain sanitary measures of a precautionary character have been taken by the Portuguese Government against the introduction of the Asiatic cholera, at this time a fearful epidemic in Egypt. From the 5th of the present month, by a ministerial decree—of which I have the honor to enclose a printed copy—the Egyptian ports of the Mediterranean were declared infected by cholera and all the Red Sea ports were declared suspected. The danger of infection at this port is not great, as Portuguese intercourse with the ports mentioned may be said to be confined to the monthly arrival at Lisbon of a steamer of the British India Company. The Spanish Government has imposed similar vigorous measures upon vessels arriving from the English ports, and a portion of the Madrid press has advised that until similar restrictions are imposed in Portuguese ports upon such vessels, an embargo be laid on all persons entering Spain by land from Portugal. Beyond the measure referred to above, no others have been taken by His Majesty's Government, as far as I am informed by the competent authorities. It is said that concert of action is contemplated by certain of the European powers as regards the continental ports of Central Europe, and that stringent measures are under consideration as regards intercourse with the ports now so painfully affected. The quarantine here is not rigorous, being of seven days only, while vessels from South American ports are subjected to eight days' detention and seclusion."

The following is a translated copy of the "Ministerial Decree" referred to in the foregoing letter :

"In consequence of information received, and in conformity with advice of board of health, all ports of Egypt on the Mediterranean are declared infected with cholera morbus from June 20th last; and also ports of the Red Sea, both Egyptian and Ottoman, are declared suspected. Lisbon, July 5, 1883."

The United States Consul at Copenhagen, Denmark, under date of July 20th, transmits to the State Department the following notice relative to the measures taken against the introduction of contagious diseases in that kingdom:

[Translation.]

"Notice is hereby given that the regulations in Second Section I. of the Law relating to measures against the introduction of contagious diseases in the kingdom, of July 2, 1880, will be enforced with regard to ships coming from all parts of Egypt until further notice is given.

"In consequence of information received that the cholera is now prevailing in Egyptian ports, and as this disease seems to have a very considerable circulation, the Regulations in Second Section No. I. of the law relating to measures against the introduction of contagious diseases in the kingdom, of June 2, 1880, will, until further notice, be enforced with regard to ships coming from, or which have been in communication with any of the ports of Egypt, or which may have received persons from, or have had persons on board from such a ship.

"This regulation will be enforced at once, and is hereby brought to the notice of all whom it may concern.

"The Ministry of Justice, July 4, 1883.

"(Signed) J. NELLEMAN."

The United States Consul at Odessa, Russia, in a letter to the State Department—July 10th—says:

"I have the honor to report that from the 13th inst. all vessels arriving at this port are to be subjected to seven days' quarantine, on account of the cholera epidemic now existing in Egypt."

The following is a list of the United States Sanitary Inspectors on duty at foreign ports, with a copy of their instructions:

At Liverpool, England.—William Kelly, M.D., Robert Jones, M.D., J. Oliver, M.D.

At London, England.—Joseph Higham Hill, M.D.

At Vera Cruz, Mexico.—Robert Mainegra, M.D.

At Havana, Cuba.—Daniel M. Burgess, M.D.

Instructions.

The Sanitary Inspector is required to visit and inspect all vessels bound for any port of the United States, and in case of the departure of infected vessels, notification of the same should be transmitted by telegraph in case the vessel is a steamer, and by mail if a sailing vessel; he will be governed in sending cable despatches by the rules for the same herewith enclosed (being an abbreviated or cipher message); he will make an abstract, weekly, of all bills of health issued at his port of all vessels bound to the United States. This report shall show the name, rig, and nationality of vessel, date of sailing, number of the crew, number of passengers, condition of crew, condition of passengers, present sanitary condition of the vessel, previous sanitary condition of vessel, and sanitary condition of the port.

All infected ships should be instructed to put in at

Ship Island or Sapelo Refuge Station before proceeding to their port of destination in the United States, thereby saving detention, as they will be sent there by the health officer of any Southern port they may attempt to enter.

The object of the inspection is to keep the Surgeon-General of the Marine Hospital Service informed of the departure of infected vessels for the United States, in order that he may notify the port of destination of the probable time of arrival of such vessel, so that precautionary measures may be taken to prevent the introduction of contagious or infectious diseases.

Every effort should be made to keep thoroughly informed of the sanitary condition of the port, and notify the Surgeon-General, without delay, of any danger that may be apparent.

SANITARY CONDITION OF WASHINGTON, D. C.—The health officer of Washington, Dr. Smith Townshend, has made a request of the District Commissioners to expend \$500 in placing the city in a good sanitary condition. Although Washington looks clean with its wide streets and beautiful parks, there are not a few by-ways and vacant lots which are teeming with filth, and need the attention of a sanitary inspector.

THE POST-MORTEM EXAMINATION OF THE LATE JACOB S. MOSHER, OF ALBANY.—The autopsy on the late Professor Mosher was held by Drs. Samuel B. Ward, Albert Vanderveer, N. L. Snow, John B. Stonehouse, William Hailes, Jr., Willis G. Tucker, and Maurice J. Lewi, coroner's physician. The result was announced as follows: "We, the physicians who were present at the autopsy on the body of the late Dr. Jacob S. Mosher, are unanimously of the opinion that death resulted from heart failure, the consequence of degeneration of the coronary arteries, and of acute endocarditis." The further opinion of the physicians is that the disease was of probably not more than ten days' duration, and was probably caused by overwork. Death was instantaneous and painless. The brain weighed a little over fifty-nine ounces, a very unusual weight. The gray matter, the residence, so to say, of the mental powers, was extraordinarily abundant. All the other organs were in an excellent state of preservation.

AMERICAN DERMATOLOGICAL ASSOCIATION.—The seventh annual meeting will be held at the Sagamore House, Green Island, Lake George, on Wednesday, Thursday, and Friday, August 29th, 30th, and 31st. Papers will be read by the following gentlemen: Dr. Piffard, "Treatment of Acne;" Dr. Hyde, "A Study of the Coincidence of Syphilitic and Non-Syphilitic Affections of the Skin;" Dr. Graham, "General Exfoliative Dermatitis;" Dr. Stelwagon, "Impetigo Contagiosa;" Dr. Robinson, "Alopecia Areata;" Dr. Duhring, (1) "On the Value of a Lotion of Sulphide of Zinc in the Treatment of Lupus Erythematosus," (2) "Report of a Case of Ainhum with Microscopic Examination;" Dr. Atkinson, "A Case of Multiple Cachectic Ulceration;" Dr. Sherwell, (1) "Pseudo-Psoriasis of the Palm," (2) "Malignant Papillary Dermatitis;" Dr. Bulkley, (1) "A Hitherto Undescribed Vegetable Parasite Found on the Human Skin," (2) "A Clinical and Experimental Study on Pruritus;" Dr. Van Harlingen, "Experiments in the Use of Naphthol."

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 13, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. V. P. GIENEY presented, in behalf of a candidate, a specimen of

BILATERAL CONGENITAL DISLOCATION OF THE HIP ASSOCIATED WITH SPINA BIFIDA.

DR. B. A. WATSON presented a specimen of

PRIMARY SCIRRHOUS CARCINOMA INVOLVING THE RIBS, ADJACENT CONNECTIVE AND MUSCULAR TISSUES, THE PERICARDIUM, AND THE HEART-WALL.

He was enabled to present this specimen by the courtesy of Dr. Walter Rae, of Jersey City, who attended the patient during the latter part of his illness, and supplied the following history: Michael E. S—, thirty-six years of age; born in Ireland; laborer; healthy man of erratic and somewhat dissipated habits. The patient informed Dr. Rae that during the epidemic of yellow fever which prevailed in Memphis in 1873 he was living in and unable to escape from the pest-afflicted district. He further adds, "I did not expect to survive this epidemic, and consequently during its continuance I was constantly drunk and frequently imbued with other vices." He gives a vague and unsatisfactory history of a supposed chancre, followed by some inflammation of the inguinal glands, from which he thinks he suffered during this period; and although no treatment was employed there has been a complete absence of any cutaneous complications or other tertiary symptoms. With the disappearance of the epidemic we are informed that Mr. S— abandoned his protracted spree, although he continued the daily use of alcoholic stimulants, but in such a quantity as to rarely produce intoxication. He began to complain in the early spring of 1882 of a sharp intermittent pain, which he located in the heart. This pain gradually increased in severity and frequency, and was soon supplemented by a slight dyspnoea. Both the pain and dyspnoea were frequently excited and always intensified by physical exertion. The disease had progressed with so much rapidity, that he found himself compelled, in the early part of the ensuing August, to abandon the performance of all labor. The pain, at the commencement of the illness was principally felt in the cardiac region, but it gradually ascended, until just previous to the death of the patient it was located in the left shoulder and upper portion of the humerus. The pain, which had been previously intermittent, became about December 1st continuous, and was described by the patient as being of a "pulling or dragging character." There was observed about the same time some unusual prominence of the upper portion of the sternum, which continued to increase until the fatal termination of the disease. The cough, which heretofore had been slight, became at this time so troublesome that the patient sought relief in the use of medicine. There was no important change noted in our patient's symptoms, although he was gradually becoming weaker, until about February 1, 1883, when it was observed that anasarca had made its appearance in the feet and ankles, which soon extended to the legs, thighs, scrotum, abdomen, etc. The lower extremities soon became so much distended that it was thought proper to freely incise the integument, which operation was followed by a profuse flow of serum. The patient had been unable to sleep in the recumbent position for two weeks prior to the making of these incisions, but subsequently he was able to resume the ordinary postures and secure the much-required rest. There appeared soon after this a severe pain in the left popliteal space, which continued some time, and seemed to be neuralgic

in character and reflex in its origin. The left upper extremity is now cedematous, although the right is normal. The relative conditions of these parts remained the same during the life of the patient. During the last three weeks of life the patient suffered from a profuse prune-juice or bloody expectoration. The autopsy was made thirty-six hours after death. The rigor mortis marked; considerable general emaciation; left upper extremity cedematous; right side of the chest is flattened laterally; bulging anteriorly of the upper portion of the sternum and thorax; this tumor is trapezoidal in shape; involves the upper portion of the sternum; extends slightly above its superior border, downward from this point three and one-half inches; its breadth is also three and one-half inches in the upper part and two inches at the lower border; it covers one inch of the sternal portion of the left clavicle and extends above the same half an inch; the right sterno-clavicular articulation is barely covered with this morbid growth; bones within the tumor are diseased and the integument covering it is perfectly healthy. The right lung contains a large abscess and is much broken down, with pleuritic adhesions over its entire surface. The liver, kidneys, stomach, and spleen are healthy.

The morbid growths were referred to Dr. William H. Welch, of Bellevue Hospital Medical College, for examination, who reports as follows: "The specimen consists of a lung [left], the heart, and a portion of the thoracic wall with the ribs. The lung shows a few spots of bronchopneumonia, a small hemorrhagic infarction in its anterior border, emphysema of moderate extent along its borders, old pleuritic adhesions, and moderate hypostatic oedema and congestion. There are a few small nodules in the periphery of the lung, which may possibly be small, secondary, cancerous nodules, although they appear more like pneumonic foci. The specimen is not sufficiently hardened to obtain satisfactory sections to determine this. The external surface of the heart presents in various places diffuse and nodular yellowish-white growths, which, in places, have invaded the muscular substances of the heart nearly to the endocardium. The most extensive of these growths surrounds the large vessels at the base of the heart, particularly anteriorly and to the right. This growth extends down so as to have invaded deeply the right border of the heart and the posterior wall of the left ventricle. At the apex of the heart is a nodule about an inch and a half in diameter. There are other nodules over the surface and in the muscular substance of the heart. The valves are not abnormal, except a little atheroma of the aortic and mitral valves. The microscopical examination of the new growths of the heart reveals a stroma of fibrous tissue enclosing alveolar spaces filled with epithelial-like cells. The structure is that of carcinoma. The adjacent muscular tissue is fatty. The portion of the chest-wall, including the bone, is infiltrated with the same kind of new growth as that involving the heart."

The diagnosis, made by Dr. Welch, constitutes the title of this paper, while the chief interest of this specimen is found in the infrequency of the occurrence of primary cancer in these organs, and the extreme difficulty with which the nature of the disease is determined before an autopsy is made. It would unquestionably be very interesting to determine (if it were possible) the point at which this disease originated before we alluded to the literature of this subject; but I fear it cannot be done in this case with either satisfaction or certainty. It is nevertheless thought that the history in this instance justifies the exclusion of the question of the origin of the disease within the bones or soft tissues of the thoracic wall. In the first stage of the disease the patient complained of a pain which he located below and to the inner side of the left nipple. The first physicians to whom he applied, and some of this number are justly regarded as eminent men in their profession, observed functional disturbances of the heart and various

morbid sounds, which caused them, without an exception, to diagnose aneurism. The swelling and pain which finally appeared in the upper part of the sternum belongs to a later stage of the disease. The origin of this disease may therefore have been in the mediastinum, pericardium, or heart-wall; but neither the specimen nor history enables us to fix it more definitely, notwithstanding the chief morbid deposits are found in the heart. The relative infrequency with which this disease occurs in the heart may be inferred from the following: "Thus in Kohler, in 9,118 autopsies, and in Tanchon, in 8,289 autopsies, cancer of the heart was observed six times by each; in Willigk, in 4,547 autopsies (of these 477 cases of carcinoma), cancer of the heart was observed nine times, and of the pericardium seven times. Most frequently carcinoma of the heart is secondary, either developed by extension from neighboring organs (mediastinum, œsophagus, etc.) or occurring as a metastatic deposit, and here frequently following the course of the vein; thus we may see it extending from the lung along the pulmonary veins into the left auricle, or along the venæ cavæ into the right auricle." Neimeyer² says: "Cancer of the heart is very rare, occurring only in general cancerous infection, or by extension from the mediastinum or pericardium. It forms circumscribed tumors, usually of the medullary, or else of the melanotic kind, which project either inward or outward, and may sprout into the cavity of the organ." Dr. Thomas B. Peacock says:³ "Cancerous deposits in the heart are of more common occurrence than tubercle. Dr. Walshe, writing in 1846, says that he had readily found twenty-five cases recorded; and more recently, in a paper in the 'Pathological Transactions,' I collected the particulars of forty-five, including in this number two which had fallen under my own notice. The earliest published examples of the disease were, I believe, those of Andral and Bayle, in 1824." Delafield says:⁴ "Carcinoma of the heart as a primary tumor is very rare. Nodules secondary to growths in the mediastinum or other regions are more common."

DR. W. M. CARPENTER remarked, with reference to Peacock's statement that "cancerous deposits in the heart are of more common occurrence than tubercle," that so far as tubercle was concerned, he had seen at the autopsy room at Bellevue Hospital, several cases of general miliary tuberculosis in adults, during the last winter, and almost without exception miliary tubercles existed in either the pericardium or the endocardium or both, and in nearly as large proportion of the cases in the cardiac muscle. He had not observed secondary cancerous growth with anything like the same frequency in the heart.

DR. C. A. LEALE presented specimens of

CHRONIC DYSENTERY CAUSED BY THE IRRITATION FROM AN ACCUMULATION OF BONES AND NUTSHELLS LODGED IN AN ABNORMAL DIVERTICULUM AT THE LOWER END OF THE SIGMOID FLEXURE OF THE COLON, WITH ULCERATIONS AT THE SEAT OF IRRITATION, WHICH CAUSED THE LADY TO BE AN INVALID FOR OVER THIRTEEN YEARS—RECOVERY AFTER THE REMOVAL OF THE SOURCES OF THE IRRITATION AND HEALING OF THE ULCERATIONS,

with the following history: Mrs. M——, aged twenty-six years, was in perfect health until thirteen years ago, when her father purchased a house in one of the most expensive parts of New York City, and lived there before the neighborhood had been built. It was subsequently found that the previous occupants had left in consequence of frequent outbreaks of malarial fevers, the endemic character of which soon became manifest in the family of Mrs. M——, causing hepatic and other chronic troubles never to be fully recovered from. At that time Mrs.

M—— had a low form of fever for nearly a year, and only partially convalesced after a change of residence. The structural change in the liver had left an obstructive circulation of the veins emptying into the portal, and whenever constipation occurred she suffered from local venous congestions and peripheral nervous irritations of the uterus, vagina, and rectum, and pains along the courses of the crural and sciatic nerves. A year after marriage she was delivered of a feeble child, with open foramen ovale, which died in three days. After a tedious convalescence she again conceived, passed nine months of great discomfort and exhaustion in consequence of her stomach and liver trouble, but at term gave birth to a large, perfect child. Last summer while at the sea-side she had a return of her dysentery, causing great depression, and although occasionally checked temporarily, it would reappear without any known provoking cause. The dysentery lasted until April 5, 1883, when, after having had twenty-eight movements in the previous twenty-four hours, she sank in a collapse so nearly fatal that restoration only followed after the most vigorous efforts, by lowering the head below the pelvis to send all the blood possible to the brain, by thoroughly washing out the bowels with warm water to free the ulcerations of the colon from all irritating mucus, then following by rectal alimentations of beef-extract, brandy, chicken-broth, and hot water, while nothing was given by the stomach. These procedures soon caused the patient to be out of immediate danger, the passages from the bowels to be checked, the vomiting to cease, and a rapid gain in strength. The rectal alimentation and hot water soon supplied the necessary nutriment, while the irritable stomach was prepared for digestion by copious draughts of warm water, to be vomited until it was well freed from the accumulated tenacious mucus contained in the stomach. To relieve the probable ulcerations finely powdered willow charcoal was given in teaspoonful doses to a gill of water thrice daily. The rapid increase of strength in a week enabled the patient to digest light diet when given by the mouth, and the improvement continued until feces accumulated in the rectum and caused a return of the old neuralgic pains along the course of the nerves leading from the sacral plexus. These pains were particularly increased in severity just before a movement, as the feces passed the posterior rectal walls; after each movement from the bowels or passage of rectal douche, the tenesmus and pain were so severe that for an hour it was almost unendurable. There was also a pain situated at the upper part of the rectum which Mrs. M—— described as her old pain in the back, of years' duration, and which had been so annoying as to prevent walking with ease, or even riding in the most comfortable carriage. This pain in the back, Mrs. M—— stated, for years had been exceedingly severe after any jolting, so much so that, although in apparent health otherwise, she was forced to renounce all such pleasures.

The general symptoms with the painful fissures of the anus caused him to suspect chronic ulceration of the alimentary canal, probably of a tuberculous character, and that several of the ulcerations at the colon were below the sigmoid flexure, where under an anæsthetic they might easily be brought into view. He therefore proposed that so soon as strength would permit a thorough examination be made, which was done on the 11th of May, when the painful fissure of the anus and ulcerated rectal lacuna, with a large varicose ulceration four inches up, were thoroughly cleansed of tenacious mucus and gently touched with pure nitric acid. The serrated ulcerated edges of the remnants of the hymen were dissected off, and dilatation of the meatus urinarius effected to remove the exposed peripheral nerves. He dilated the os uteri and cleansed out the tenacious mucus, then gently applied nitric acid to the cavity. After neutralizing all excess of acid with the bicarbonate of soda, and washing off the external parts with warm water, and emptying the bladder, she easily came from

⁴ Post-Mortem Læs. and Morbid Anatomy, p. 113.

under the influence of ether. Half a grain of morphine was given, and to the external parts warm water dressings were applied.

On the following and several successive days we were very much disappointed to find that the old pain in the rectum and left iliac region had rather increased than otherwise; the urine was drawn off for a few days by catheter. All pain except that in the rectum and back had entirely disappeared on the fifth day, when dysentery again reappeared, accompanied with pain exceedingly severe and running from the cæcum down the thigh along the course of the sciatic nerve. On the 18th he visited her, prepared to give the anæsthetic to further examine and see the result of former treatment, but her great depression and weakness from the continued dysentery caused a postponement until the following day, May 19th, when ether was again given, and all the ulcerated parts previously treated were found to be in a good condition, enabling him to make a more extended examination up the colon. The largest size duck-bill and cylindrical speculums were each used and all parts exposed to view. Above the varicose ulcerations were found in a healthy condition. Thinking that he had not reached the point of pain continuing after the first operation, he thoroughly dilated the anus, drew down the rectum, and after digital dilatation of its walls, passed up to the lower part of the sigmoid flexure, when he entered a cul-de-sac about two inches in depth, *into which he passed his forefinger*, and came in contact with several sharp, hard foreign masses lodged in the cavity. This cavity proved to be an artificially formed diverticulum at the lower end of the sigmoid flexure, and contained one bone an inch in length and five other irregular-shaped bones, one being triangular, having exceedingly sharp cutting edges. There were also other small foreign masses. All these were easily removed after dilating the mouth of the diverticulum, and are presented to the Society this evening.

The three larger bones he found, thanks to Professor W. K. Parker, F.R.C.S., London, to be the radius and bones of the manus, and the sharp triangular bone of the digit of a bird of the size of a quail ("Encyclop. Brit.," ninth ed.). As Mrs. M—— stated that she had not eaten birds for months, and as the pain in the back had been of years' duration, and entirely ceased after their removal, he surmised that these bones had been arrested at a weak ulcerated part of the bowels when she had her original fever and diarrhoea, thirteen years before; that from the frequent straining this diverticulum had formed at the inferior end of the sigmoid flexure, where a normal pouching exists, and by the tension had increased; that these bones had been the sources of irritation, and were prevented from being extruded by a subsequent and partial invagination of the bowel above, and were the cause of the dysentery. These conclusions are strongly fortified when we consider that the original pain in the back and colon neuralgia and the tenesmus entirely disappeared after the removal of the sources of irritation.

Dr. Leale also presented three

AXILLARY GLANDS,

which he had removed from a patient from whom he removed a cancerous breast one year ago, and the wound healed entirely. This woman nursed a patient from whom he removed a cancerous breast three years ago. At the time she nursed the lady she had no trouble whatever with her breasts, but about two years afterward the scirrhus developed and was removed.

DR. F. N. OTIS presented a specimen of phosphatic calculus removed by lithotripsy, and used Bigelow's evacuating apparatus with a great deal of satisfaction so far as results were concerned. It had occurred to him, however, that if a less expensive instrument could be devised, which was efficient, it might and would be acceptable. He did not think that Bigelow's instrument could be improved. But after spending considerable

time with a view to improving Clover's instrument, the idea occurred to him that an instrument acting on the same principle as Bigelow's might be constructed somewhat differently, be of much smaller size and less expensive. The result of his labor had been

AN EVACUATING INSTRUMENT WITH AN INDEPENDENT AIR-CHAMBER,

which he had used experimentally with great satisfaction. [It was exhibited to the Society.]

Dr. Otis also presented one entire skull and a part of another, sent to him from the Army Medical Museum at Washington for an opinion concerning the nature of the disease that could have produced the manifest localized loss of bony tissue. There was evidence of loss of the diploë *without* any loss of the external table, a simple sinking in of the external table, leaving apparent elevations with alternating depressions, which is not found with any disease other than syphilis.

DR. LEALE remarked that it would be interesting to know from whence the bones came, as they might aid in solving the question of Dr. Jones concerning the existence of syphilis in this country before the advent of the white man.

DR. OTIS was of the opinion that most, if not all of the prehistoric syphilis would turn out rather fanciful.

DR. L. EMMETT HOLT presented a specimen of

INTUSSUSCEPTION,

with the following history:

A plump well-nourished child, aged two and a half months, was brought to his dispensary clinic on Monday, June 11, 1883. The child, the mother stated, had been quite well until Sunday evening. The bowels had been regular, and she had given it nothing but the breast. She had partaken herself quite freely of cabbage at noon, and to this in part she attributed the child's indisposition. It was taken at first with vomiting, which had continued ever since; first the contents of the stomach and afterward a thin greenish fluid was ejected. The child was restless during the night, nursed but a few moments at a time, and slept very little. She had during the day, Monday, four quite large stools, which consisted principally of blood mixed with a little mucus. Straining and pain seemed to accompany the movements. On examination he found the child rather drowsy and listless; the clothing was stained with the greenish fluid she had been vomiting all day. The prostration was not specially marked. The rectal temperature was 103½° F. Unfortunately the examination of the abdomen was not recorded, if indeed one was made. The case was regarded as one of dysentery with a considerable amount of gastritis, and simple remedies were prescribed. He directed the mother, however, to report to him the following morning. She did not do so, and the case had quite passed out of his mind, when she came in on Thursday for a death-certificate, saying that the child had died early Wednesday afternoon.

She gave the following account of the case after her visit to the dispensary: The vomiting persisted up to the morning of the day of her death. For nearly twenty-four hours before, the vomited matters were of a brownish color and had a very bad, but not a fecal odor. After Tuesday morning absolutely nothing passed the bowels. The abdomen became very rapidly distended with gas; and the extremities cold. The child was restless, tossing from side to side much of the time. On Tuesday evening it was taken with a convulsion, which was repeated during the night. The following day the child died in convulsions after an illness of a little more than sixty hours. No other medical advice was sought.

From the history given he made a diagnosis of undoubted intussusception and refused to grant a certificate without an autopsy, which was finally permitted. As nothing bearing upon the case was found in the other organs

he confined himself to the examination of the abdomen. Before opening this, careful exploration was made by palpation to discover, if possible, any tumor. From the great tympanites it was out of the question. On opening the cavity the small intestines, distended with gas to a size equal to that in a healthy adult, filled the wound. A small amount of reddish serum was found in the peritoneal cavity without odor, perhaps a couple of ounces in all. The lower part of the large intestine was empty and following this up he found, a little to the right of the spine and lying quite closely against it, in about the region of the hepatic flexure of the colon a tumor about two inches long and one inch in width. The tumor was tightly held down by the mesentery. The intestine was healthy in its external appearance, not even showing much congestion. No evidence of peritonitis was discovered. The tumor after removal was found to be perfectly solid to the touch. An unsuccessful attempt was made to force water through the obstruction from both directions. The distal extremity of the tumor was rounded, and showed a slit-like opening a little to one side of the middle. This was believed to be the ileo-cæcal valve, as was afterward demonstrated. A probe was passed without much difficulty through the whole tumor, entering this opening. No orifice corresponding to the vermiform appendix could be found. The intussusception was exceedingly tight. A traction force of several pounds was required for its reduction, and some of the longitudinal muscular bands gave way before complete reduction was accomplished. The invagination began at the ileo-cæcal valve, about two inches of the ileum passed through this into the cæcum, which itself then was invaginated into the colon and then the colon into itself. The invaginated part then was composed of two inches of ileum, the cæcum, and six inches of the colon.

One point of interest attaching to the case is the age of the child. Of somewhat over ninety cases of intussusception reported by Smith and West only three occurred in the first three months of life. From three to twelve months is the most frequent period. Nearly one-half their cases occurred between those ages.

The small size and the somewhat unusual position would have made the diagnosis of the tumor somewhat difficult, even before the great tympanites developed. The general symptoms, however, were so characteristic as to leave no room for doubt as to the nature of the lesion. From the difficulty experienced in the reduction post mortem it would appear that injections during life would not have been likely to succeed.

DR. LEALE referred to an autopsy which he made on the body of a child less than *one month* old, in which a similar condition was present, induced apparently by a dose of castor oil.

The Society then went into executive session.

ANTIHELIOIS. — Dr. MacCormac, of Belfast, has recently written a short article with the above title. Having called attention to the unexplained immunity from sunstroke enjoyed by Hindoos and Africans the writer proceeds to make what he apparently believes to be an original suggestion. Although the cooling of heated air supplied to chambers is no new thing, yet we cannot but re-echo the suggestion made by the writer mentioned. By mechanical power the hot air of tropical climates might be drawn through ice chambers or other cooling apparatus, and then sent into the dwelling apartments, workshops, barracks, tents, hospitals, factories, churches, assembly-rooms, and sick-rooms. Wind, water, steam, hand, or Mouchot's sun-engine might each find its appropriate application under different circumstances. Dr. MacCormac regards such an arrangement as more thorough and enjoyable than the tatties and punkahs of India. The importance of temperance in food and drink is wisely insisted upon; without this, coolness would not suffice to prevent the effects of intense heat.—*Lancet*.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, June 1, 1883.

BEVERLEY ROBINSON, M.D., PRESIDENT PRO TEM. IN THE CHAIR.

DR. V. P. GIBNEY read the history of a

CASE OF COSTO-VERTEBRAL PERIOSTITIS, DORSAL REGION, TRAUMATIC.

The speaker said: The case I am about to present furnishes some interesting points from a diagnostic point of view. Such cases I believe to be rare, and hence my excuse for placing it on record. Often a vertebral osteitis (called by one or two authorities in orthopedic surgery with remarkable persistency a *spondylitis*) develops in a child and a fall or sprain is reported as arising from trauma—it doesn't make any difference how long the interval. To find, I think, one of these chronic bone-lesions, central in its incipency, following *closely* upon an injury, is certainly, in my own experience, very rare. Acute peripheral lesions I do find, and the connection between cause and effect is quite close.

The little girl whose case forms the text for these remarks is nine years of age, and she came under my observation on January 24, 1883. She was decidedly nervous, and from the general bearing of her mother I concluded that she was entitled to this diathesis.

Her complaining for the past four weeks had had the spine as the objective point. On examination I found a small cyst-like body, not any larger than a split peanut, lying over the transverse process of the eleventh dorsal vertebra, left side, and to all appearances overlapping the articular end of the tubercle of the rib. This small tumor was sessile, was subtegumentary, and was connected, I believe, to the periosteum. The soft tissues immediately adjoining were infiltrated to a moderate extent, and the localized tenderness was quite marked.

The patient stooped very awkwardly and I began to suspect some disease in the body of the vertebra. There was no tenderness on concussion, and the spinous process did not participate in the deformity.

The history enabled me, apart from the signs, to eliminate any chronic bone disease in the diagnosis. While in perfect health she experienced one day, four weeks before this visit, a pain in her back while lifting her elder sister. She remained in bed next day, so much soreness did she feel, and kept her bed for one week. The pain was very acute at times, especially on movement.

One of my assistants, in whose opinion I always place much confidence, leaned to ostiitis of rather an acute nature, and I determined to apply an apparatus as a matter of precaution. Pending the making of the same I ordered a counter-irritant and put on a roller with cotton-wool beneath.

On February 20th I find that it feels and looks more cyst-like and a hypodermic needle is introduced for exploration. This little operation is unsatisfactory, on account of the fright of the girl, and I get only a little blood and lose the patient's confidence.

When I saw her again it was March 31st. An abscess had formed in the meanwhile, had opened, and there was now a small sero-purulent discharge therefrom. The brace was removed and a poultice was ordered.

On April 11th the opening was larger, and through it protruded a mass of granulation tissue which required a caustic.

On the 17th I found projecting through the opening, a small shell of bone, evidently exfoliated from the tubercular process or the rib.

The subsequent history is briefly told. The ulcer healed in a few days. I kept her under observation a couple of weeks longer, and finding a complete cessation of all signs and symptoms, discharged the case.

DR. HENRY F. WALKER read a paper entitled

A CASE OF IMPERFECT DEVELOPMENT OF THE PARIETAL BONES OF AN INFANT.

The speaker said: In January, 1883, I attended a primipara in confinement. She was the wife of a man of good physique, but was herself frail and of a very nervous temperament. Neither parent gave history of previous illness or marked diathesis. The labor was prolonged but perfectly natural, and completed without assistance. The caput succedaneum was quite prominent on the vertex to the child's right. It was rather larger than usual, but not larger than one sees without anxiety. I assured the mother that in a few days the child's head would assume a normal form.

On my subsequent daily visits the child was usually sleeping, lying on the back, and was not disturbed. Ten days after its birth the nurse said that the mother was worried because the child's head still showed marked deformity. I then examined it carefully and found that the parietal bones were imperfectly developed. The sagittal suture and the sutures between each parietal and the occipital bone were as perfect as usual, and the fontanel was not of unusual size. But parallel to the sagittal suture in each parietal bone, about three-fourths of an inch from the median line, was a space where the only covering of the brain seemed to be fleshy tissues. This allowed a protuberance of the cranial contents. The tumor on each side was three inches long vertically, the left was three-fourths of an inch and the right one inch wide, while the projection above the general surface was nearly half an inch. The bordering edges of bone could be easily determined, while the firm bone uniting in the sagittal suture and which divided the spaces could be clearly felt. The child was born at full term and no occasion for arrest of development could be found.

I gave a guarded prognosis. While I continued in daily attendance on the mother no change was perceptible. Two months afterward I was asked to inspect and pronounce upon the child's condition. I found that the bony formation on the right side was nearly perfect. The head was a little protuberant there, but the bony case was quite firm and resistant, though evidently thinner toward its centre. The smaller space, that on the left, was completely filled. The bone, however, had here united at an acute angle, making a sharply defined ridge three-eighths of an inch in height above the general surface. Had it not been for this ridge, the absolute proof of the correctness of the original diagnosis, I might have been inclined to think that I had mistaken double hæmatoma for the tumor from non-developed bones. But the bony ridge seemed to me proof positive of the correctness of my first opinion.

At three months the child was well, though with a head of slightly peculiar form.

In response to the query whether the condition might not have been a hæmatoma, Dr. Walker said that he had had that possibility in mind all the time, and the evidence seemed to him conclusive that it was not one.

DR. F. P. KINNICUTT reported a

CASE OF DIABETIC COMA.

[This will appear later in THE RECORD.]

DR. H. F. WALKER said that a few years ago he had a case in which albuminuria and glycosuria seemed to alternate. The patient finally died of Bright's disease.

DR. KINNICUTT said that he had recently observed another case of diabetes in which the

NERVOUS SYMPTOMS

were very marked. The patient was a lady who had had the disease for seven or eight years. During that time she had frequently had attacks of paresis involving different portions of the body. She had first three successive attacks of facial paralysis. The first attack developed

very suddenly with no other symptoms and the paralysis seemed to be peripheral, since the muscles in the upper part of the face were affected as much as those in the lower. The symptoms lasted for only about a week when they disappeared almost entirely. A few weeks later a facial paralysis on the other side of the face appeared. This also rapidly improved, and was followed by a third attack. A short time ago, without any warning, she suddenly developed a left hemiplegia affecting both the upper and lower extremities and face in a very marked degree. This did not improve; it lasted about ten days, when the patient suddenly had an attack of syncope and died. She was a very large person with, probably, a fatty heart. Referring to the subject of diabetic coma, he said that as to

PREVENTION

it is well known that the attacks are more apt to occur after great physical exertion. Patients sometimes develop them after being brought to a hospital from a long distance. They also occur when the sugar has fallen in amount.

DR. MCBRIDE said that he had not seen any case of diabetic coma, but he should be very much inclined to make use of

VENESECTION WITH ARTERIAL TRANSFUSION.

He had seen such brilliant success with this method occurring in coma from poisoning by illuminating gas that he felt great confidence in its efficacy in diabetic coma. With the perfection now obtained in the technique of transfusion, especially arterial transfusion, the operation is almost entirely devoid of danger, and is one which every physician should be able to perform.

DR. KINNICUTT said that he had tried transfusion, although it had not been preceded by venesection.

DR. MCBRIDE thought venesection should first be practised. Arterial transfusion was preferable because it was less dangerous. The radial artery is usually selected and the blood transfused *toward the heart*. In cases where the blood has been transfused toward the periphery thrombi have resulted.

DR. C. L. DANA reported his experience with

PARALDEHYDE AS A HYPNOTIC AND ANODYNE.

The introduction of paraldehyde by Cerville, of Palermo, and its use by Morselli, of Turin, and others was referred to. A specimen of the drug was shown. It is a transparent colorless liquid, with a penetrating odor and taste, suggesting Hoffman's anodyne. Its formula is $C_6H_{12}O_3$. It dissolves slightly in water, but mixes with it very readily. Dr. Dana had been unable to procure any in the city, and it was made for him out of Merck's aldehyde, by Dr. Chevaillier, Lecturer on Chemistry at the Woman's Medical College of the New York Infirmary.

He first tried it on a pup six months old, giving it a gramme by the mouth. The animal was at first much excited, running around and stumbling as if intoxicated. It showed no signs of pain or gastric disturbance. Its intelligence was not greatly disturbed; it would come when called. Pulse ran up from 130 to 200; respiration was 20 to 24 and labored. In about twenty minutes it lay down and went to sleep. Pulse, 140; respiration, slower (18), and with labored inspiration. The animal was easily roused, walked around, then went to sleep again. Slept about two hours.

Having demonstrated its innocuousness, the drug was prescribed in a number of cases. Notes were given of thirteen; nine times it was given for insomnia, twice for its general sedative effects, twice as an anodyne in neuralgia. In six cases it acted very well as a hypnotic, in two it was helpful, in one it failed. Large doses (*i.e.*, above three grammes) were not prescribed. Given in sciatica and supraorbital neuralgia it caused relief of pain temporarily. As a general sedative in "nervousness" it acted remarkably well in one case, and gave

some relief in the other. The dose was $\bar{c}$ ss. to $\bar{c}$ j. well diluted; there were no bad after-effects.

Dr. Dana thought that it was a somewhat less sure and powerful hypnotic than chloral. It was also more disagreeable to the taste. It had the advantage of being safe, of having no bad after-effects. It would probably prove useful in those cases where chloral fails, or is for any reason contra-indicated. At present it is rather expensive.

Dr. McBRIDE asked what were the objections to chloral.

Dr. DANA said that chloral was not without danger; that it was disagreeable, and that some persons could not take it. In fact, he had investigated the value of paraldehyde largely because he had a patient who had attacks of insomnia. Chloral produced sleep, but made him sick all the next day. Bromide of potassium kept him awake unless used in large, long-continued doses.

Dr. McBRIDE thought that chloral could be used with greater freedom than had been supposed. He had given it in pneumonia with dilatation of the heart in doses of one hundred and sixty grains in twenty-four hours (with digitalis), and he had lost in a great measure the dread which he had had of its evil effects. He usually gave it, if indicated, in typhoid cases. In some obstinate cases of insomnia, chloral in doses of five grains with $\bar{c}$ ss. of bicarbonate of soda (as suggested by Mitchell), was often successful.

Dr. KINNICUTT had given one hundred and twenty to one hundred and forty grains of chloral a day to a boy of fourteen, suffering from a very violent chorea.

Dr. McBRIDE had used chloral hypodermically several times in convulsions, and it seemed to him to be the remedy for convulsions. He used a solution of one part chloral to four parts water, injecting a syringeful. It had never produced any abscess. The speaker had also found

SMALL DOSES OF CHLORAL IN URÆMIC DYSPNEA

very efficient. Three to five doses generally secured relief. He had found it even better than morphine.

Correspondence.

OUR CANADA LETTER.

(From our Special Correspondent.)

MEDICAL SCHOOLS FOR WOMEN—PROVINCIAL BOARD OF HEALTH FOR ONTARIO—SUMMER SESSIONS—QUACKERY IN MEDICINE.

TORONTO, CANADA.

For some time there has been a good deal of agitation in favor of medical colleges for women. This has grown out of what is called the Kingston trouble. During the session of last winter several ladies were attending the medical school in Kingston. Exception was taken by those ladies to some remarks made by the lecturer on physiology. The men in the class became noisy and made statements that greatly offended the ladies. For some time the work of the school was at a standstill. The students threatened to leave the school. After some negotiations between the students and professors the matter was adjusted by the latter agreeing to give separate instructions to the men and women. This difficulty made it apparent that co-education would not work, and so both Kingston and Toronto are on the eve of organizing a college for the fair sex. Dr. Lavell has been chosen as Dean of the former, and Dr. M. Barrett of the latter. It is expected that both schools will be opened for lectures this coming winter. There has been a good deal of talk about the usefulness of having women educated in medicine for the purpose of sending them out as missionaries to foreign lands. This may seem very fine, but after all it is the question of dollars and cents that is at the bottom of the whole move, both on the

part of the medical men agitating the schools and the ladies who wish to secure medical qualifications. There cannot be any doubt in the minds of all who think calmly on the matter, but that these young female doctors will locate on our streets and in our villages and towns, whereas those who go abroad, as medical missionaries, will be about as numerous as the Howards and Peabodys. The move is certainly very unpopular with the medical profession at large in this country.

The Provincial Board of Health for Ontario was established a little more than a year ago by an Act of the local Legislature. In the short time that it has been in existence it has done much good work. One of the leading objects it has had in view is the establishing of local boards to take charge of matters of public health over small areas. One point, however, must be regretted, that the salaries of the gentlemen on the board are not sufficiently large to enable them to give their whole time to sanitary matters, instead of dividing it between the duties of public office and private practice. The smallness of the salaries at present granted should be protested against.

Several of the Canadian medical schools have organized a summer session. So far these have been very successful, and in future they will form a prominent part of the education of medical students. The class of lectures given are distinctly practical, and on parts of the work that could not receive sufficiently full attention during the winter months. This form of summer work will have a great influence in raising the standard of medical education.

At the recent meeting of the College of Physicians and Surgeons, a good deal of discussion took place on the question of quackery. Various remedies were suggested, among which might be mentioned the plans of asking Government to grant no patents for proprietary remedies, or imposing a heavy tax upon such preparations; or, again, of having an inspector appointed, who would condemn all worthless compounds. Perhaps the best plan was that of compelling the manufacturer, under heavy fine, to print distinctly on the wrappers the exact composition of the mixture. This would certainly kill most of the nostrums for sale in this country. Another burning question was, what to do with a nondescript and apostate class of practitioners, who advertise special cures, and fill the columns of our dailies with cases successfully treated. No doubt some action similar to that taken in Britain, would prove wholesome—of removing the name from the register of any person who advertises a remedy of special virtues, the secret of which he keeps to himself. It is to be hoped that fearless action will be taken soon with this class.

"COPPER AND CHOLERA."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: There appears to me another explanation of the immunity enjoyed by workers in copper and brass than that suggested by Dr. Peckham in your issue of August 18th, namely, the fact that in most cases mineral acids especially *sulphuric acid* is more or less used by them, and that they come into contact with acid salts in much of their work. Anyone who has had occasion to visit a brass foundry has seen the pickling-vats in which, with the aid of this acid, castings are deprived of the "skin" of oxidized metal and fused sand, after coming from the moulds. He may also have noticed that in many of the processes of brazing or soldering joints, mineral acids are used to give a bright and clean surface. This is especially the case when electro-plating or hand-plating is carried on.

It is not difficult to understand that in one way or another these acid substances gain an entrance to the alimentary canal, and that they there prevent the development or destroy the vitality of cholera-germs.

As an opinion of the power of mineral acids to prevent the development of cholera, allow me to quote

Surgeon Eli McClellan, of the U. S. Army, one of the authors of the Government Report on "The Cholera Epidemic of 1873 in the United States," p. 32: "The experience of the writer is strongly corroborative of the beneficial results which may be obtained from the use of sulphate of iron and dilute sulphuric acid as prophylactics during an epidemic of cholera." In another work, intended for popular use¹ Dr. McClellan writes as follows: "When the specific poison of cholera has been swallowed and comes in contact with healthy gastric juice, the latter, by virtue of its acidity, utterly destroys the poison. If, however, the gastric juice has not its normal acid reaction, then the specific poison, meeting only alkaline fluids, is able to reproduce itself," etc. He subsequently² advises the use of a mixture of one ounce of sulphuric acid to a gallon of water as a disinfecting solution for "cholera stuff" and soiled clothing; and also says (p. 94), "A mixture of aromatic sulphuric acid and laudanum is about the most efficacious [prophylactic] which can be employed."

If we accept the opinion of so able an authority respecting the value of sulphuric acid as a preventive of this disease, is it not easier to account for the immunity of copper-workers, who use it almost constantly in their art, than to presume that the metal itself affords the protection.

F. A. CASTLE, M.D.

102 EAST FIFTY-SEVENTH STREET, NEW YORK.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 11, 1883, to August 18, 1883.

BAXTER, JEDEDIAH H., Chief Medical Purveyor, United States Army. To proceed to San Francisco, Cal., via St. Louis, Mo., on public business connected with the Medical Department, and on completion thereof will return to his station. S. O. 185, par. 1, A. G. O., August 11, 1883.

BARNETT, RICHARDS, Captain and Assistant Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 149, par. 2, Department of the East, August 10, 1883.

BURTON, HENRY G., Captain and Assistant Surgeon. Relieved from duty at Fort A. Lincoln, D. T., and assigned to duty at Fort Assiniboine, M. T. S. O. 141, par. 1, Department of Dakota, August 11, 1883.

BENHAM, R. B., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Assiniboine, M. T., and assigned to duty at Fort A. Lincoln, D. T. S. O. 141, par. 2, Department of Dakota, August 11, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending August 18, 1883.

BRIGHT, GEORGE A., Surgeon. Temporary duty at Naval Rendezvous, Philadelphia, Penn.

NEILSON, JOHN L., Surgeon. Temporary duty on Receiving-Ship Franklin, Norfolk, Va.

MARTIN, WILLIAM, Assistant Surgeon. Navy Yard, Pensacola, Fla.

DIARRHOEA IN INFANTS.—Dr. Lewin has found great success in the treatment of diarrhoea in young infants by giving them soluble albuminate of tannin, made by adding white of egg to a solution of tannin; the white of egg must be previously beaten up with some water.—*Ther. Gazette*.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 21, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
August 14, 1883.....	0	53	28	2	36	25	0	0
August 21, 1883.....	0	45	32	3	20	24	0	0
<i>Deaths.</i>								
August 14, 1883.....	0	10	4	2	16	15	0	0
August 21, 1883.....	0	11	14	3	10	15	0	0

PASTEUR'S PENSION.—On the 12th inst. the bill increasing M. Pasteur's pension from 12,000 to 25,000 francs, with reversion to his wife and children, passed the French Chamber without a division. In reply to certain dissentients, M. Paul Bert cited the English grant to Jenner, and scouted with warmth the charge of sordid motives brought against Pasteur.

THE TREATMENT OF TREMOR.—According to M. Feris, of Brest, veratrin has the property of causing various kinds of tremor to disappear, and that in the space of ten days or a fortnight. It has been employed in disseminated sclerosis, alcoholism, and adynamic states. The dose is four pills per diem, each containing half a milligramme of the alkaloid.

FRENCH TREATMENT OF CROUP.—Dr. Jules Simon treats croup as follows: As soon as the malady is diagnosed he touches the throat with lemon-juice, or a solution of muriate of iron every two hours. Every three hours he washes the part affected with a solution of borax (two drachms to the ten ounces). At the same time the atmosphere of the room is charged with atomized phenic solution, a stimulant nourishment is given, and three to five drops of tincture of iron administered every three hours. When dyspnoea becomes apparent an emetic is to be given, but if the symptoms are not relieved tracheotomy must be performed without delay. The results of the operation are not, however, very satisfactory, as when the child is under two years a fatal termination is the rule, whereas above that age one out of five recovers. The after-treatment consists in placing a piece of tarlatan over the canula, warming the room, and administering beef-tea and tincture of iron. The removing and cleaning of the canula should be done by an experienced person, it might be definitely removed after the eighth or tenth day. M. Simon considers that chlorate of potash is of little use in croup.

THE EXTENT OF CROSS-EXAMINATION OF MEDICAL WITNESSES.—The courts of Pennsylvania are more strict in regard to the proper extent of cross-examination of witnesses than those of this State. It was held not long since in a Pennsylvania suit that a physician called as an ordinary witness in a case involving the question of professional negligence, could not be cross-examined as to his knowledge as an expert. In this State considerable freedom of cross-examination is allowed, and questions of this character would, no doubt, be admissible.

THE RIGHT OF PREVENTING PERSONS FROM ATTENDING FUNERALS.—A curious case involving the right to prevent persons from attending a funeral was recently decided in Rhode Island. The facts were that the plaintiff's wife had been enticed away from him by the defendants, and while absent from him she had died; the

defendants conducted the funeral services, and refused to allow the plaintiff to see her body or attend the funeral. Suit was then brought for damages against the defendants. The Court refused to sustain the action in the following opinion: "We find no ground, either in reason or authority, for holding that any person has a right to enter the possessions of another without his consent for attending a funeral. It is suggested that the public nature of funeral ceremonies implies a license; but such license, if one arose in this case, was revocable, and was clearly revoked by the subsequent conduct of the defendant as set out in the court. It is also suggested that the wrongdoing of the defendants in enticing away the wife raises a license of which the plaintiff may avail himself under this court; but we think that the right of the husband in this regard was at most a right to have the custody of the body of his wife, and to order the funeral ceremonies himself in his own possessions, and that the license, if any was implied, was to enter the premises of the defendants for the purpose of assuming such custody and removing the body for that purpose. But in this case there is no allegation of demand for the body or refusal to deliver the same; the only allegation being that the plaintiff was prevented from attending the ceremonies which were proceeding under the charge of the defendants."

IODOFORM IN THE TREATMENT OF LEUCORRHOEA IN CHILDREN.—Dr. Weissenberg claims excellent results in the treatment of vulvo-vaginitis in girls by iodoform (*Memorabilien*, June 9, 1883). His method is the following: The child is bathed for the first few days in lukewarm water, and the vagina is syringed out two or three times a day with lukewarm infusion of chamomile. When the inflammation is somewhat reduced by this treatment, usually after three days, the vagina is dried with salicylated cotton on a uterine sound, and then an iodoform pencil is passed up above the hymen. In two days, after a bath, this procedure is repeated, after which the cure is in most cases complete. Instead of the pencil, iodoform in powder may be strewn in the vagina, with sometimes better results.

INFANTICIDE AND ABORTION IN THE HAWAIIAN ISLANDS.—When the Boston missionaries first settled among the natives they found infanticide practised to an alarming extent, mothers deliberately smothering, strangling, or burying alive their newly born. Mrs. Judd, the wife of that Dr. Judd to whom the Hawaiians owe their present form of government, mentions the frightful extent to which infanticide was carried in 1828, and records a case under her own observation, where a mother was known to have buried alive eight out of ten children born to her. Civilization, however, has somewhat refined the native taste, so that abortion has superseded the more barbarous method, and the manner in which they induce it is well worth relating. The unfortunate woman is placed upon her back on the floor, and the officiating *Kahuna*, or medicine woman, taking a stone in either hand, proceeds to knead and squeeze the abdomen, endeavoring to get the uterus between the stones. Next she gets upon her victim's abdomen with her knees, and walks all over it, so to speak. This violence generally brings on flooding, and in a short time abortion, but alas! frequently at the expense of the patient's life, though in one case which was cited to me dumb-bells replaced the stones in the operation, great violence being done, and yet the woman went on to term and gave birth to a healthy child.—DR. HEFFINGER in *Boston Medical and Surgical Journal*.

THE LONDON "TIMES" ON THE MODERN MEDICAL STUDENT.—Commenting on the fact that one of the members of the Royal Family presided at the graduating exercises of St. Thomas' Hospital, the *Times* says: "The medical students of to-day will be the practitioners of a few years hence; the men on whose care and skill the preservation of precious lives must frequently de-

pend, and who will become, in an infinite number of matters, the most confidential and most trusted advisers of all classes of the community. Everything which elevates them in their own eyes, which renders them more conscious of the importance of the duties they will be called upon to discharge, and more zealous in preparing to discharge their duties thoroughly, is so much direct gain to the community. And it may be that such consequences will in some degree flow from the countenance and the favor of Royalty. Thirty years ago the medical student was a familiar character in fiction, and both Charles Dickens and Albert Smith, according to their several lights, described the aspects under which they were accustomed to regard him. Bob Sawyer will remain as a type of a class as long as English literature endures; but he is a type of a class which has long ceased to exist. The medical students of to-day can hardly be said to present any salient characteristics, or to differ in any appreciable degree from the student of any other profession, unless it be that there are few others in which the examinations are of equal severity or of equal range, or in which such laborious preparation is necessary for the attainment of success. The mere riotousness of youth, the natural exuberance of the years from seventeen to twenty-one, has found outlets of which Bob Sawyer had no knowledge; and athleticism, volunteering, and bicycles have superseded tavern orgies and nocturnal mischief."

AN ACTIVE PRINCIPLE OF ERGOT has been obtained by Gehe & Co., Paris. It is called ergotin, and it is said to have very powerful hæmostatic properties. It is very expensive, however, one gramme costing about forty dollars.

A BON-MOT OF LUDWIG.—Professor Ludwig, the well-known physiologist, of Leipzig, is one of the few German professors who can say a bright thing occasionally. Some time ago, Professor Marey, of the College of France, was paying a visit to the German universities, and called upon Ludwig, who paid him the honors of the institution. Marey showed himself particularly surprised at the great size of the frogs which were submitted to experiment. "That ought not to surprise you," said Ludwig. "In France you have the big Marey (swamp), but the little frogs; we have the little marais, but the big frogs."

A NOVEL LARYNGOSCOPE.—Dr. Thomas Dimock writes as follows to the *Therapeutic Gazette*: "One of the best methods for examining the throat without the aid of the ordinary laryngoscope is the following: Bring the patient near a good light of any kind, and after the mouth has been opened place on the tongue a depressor, then request the patient to yawn. The larynx will immediately rise up and every part necessary to be seen will be brought fully into view. The nose should be held, as this compels breathing through the mouth. Thus the velum pendulum palati is raised, the anterior and posterior pillars become widened, exposing the back of the tonsils and pharynx. The tongue must be pressed downward very gently, as it always resists harsh treatment." The question naturally occurs, Suppose the patient will not yawn?

SMALL-POX, PETROLEUM AS AN ECTROTIC.—Dr. Kanski states that he has obtained excellent results, even in the confluent form of small-pox, by painting the skin with a solution of petroleum in olive oil, one to three or four.—*Przegląd Lekarski. Ther. Gazette.*

A NEW USE FOR CHLORAL HYDRATE.—B. Bonatti recommends chloral hydrate in combination with senna as a rapid and safe drastic cathartic. He prescribes:

R. Infus. sennæ fl ℥ x.
Chloralis hydratis gr. xxiv.-l.
Syrupi fl ℥ j.

With this he obtained an action where cotoin and jalap had failed.—*D. Med. Zeitung. Pharmaceutische Centralkalle. Ther. Gazette.*

ATONIC DYSPEPSIA.

By J. MILNER FOTHERGILL, M.D.,

EDINBURGH, SCOTLAND.

HONORARY M.D., RUSH MEDICAL COLLEGE, ILLINOIS, ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

DYSPEPSIA is a malady which presents itself under various aspects. In one case there is great irritability of the digestive organs, they are easily upset by any unsuitable food, by exposure to cold, or by any great emotion; in another the digestive organs are enfeebled by venous engorgement, as in the gastric catarrh of valvular disease, or a failing heart; in another case there is simply want of tone in the digestive organs with a defective or capricious appetite. These are three well-marked varieties; there are others equally marked which need not be alluded to at present.

When the dyspeptic patient presents himself or herself before the physician, the first thing to be done is to know something about the family history, the history of the individual, the occupation, the opportunities for taking food, the condition of the teeth, and the state of the bowels. One is just as important as another. An elaborate plan of treatment may be rendered entirely futile by omitting to ascertain the condition of the teeth, which, perhaps, is such that efficient mastication is simply a physical impossibility. Without some rectification of this defect all the rest is useless, no matter how elaborate. On the other hand, it is well to investigate the family history, and learn how far the family is one in which diseases are developed which are linked with failure of the nutrition. If such family maladies exist, then the case will probably be comparatively intractable, as contrasted with a case where the family history has other associations. Then the history of the individual is important. If he be one who has lived long, where inappropriate food has been taken for a lengthened period, such as a stock-rider in Australia, or out West, who lives on damper with salt pork, relieved by tinned provisions, until the digestive organs have been thoroughly upset; then the case will require time for the organs to recover themselves. In another case the individual will have endured great mental tension for a considerable time without any failure of the nervous system; but the digestive organs have given in. Thus in one case, well known to me, the patient underwent two years of the most intense strain in Wall Street, his nervous system did not suffer in the slightest, but his liver had almost lost its power of dealing with albuminoids. Another for seven years worked hard building up a business in Russia, with the result that he is a confirmed dyspeptic, with a colon very readily offended. A third carried all before him as a civil servant in India, but has now for some years been laid upon the shelf an incurable dyspeptic—or, at least, no one has been able to endow him with the capacity to digest enough to enable him once more to work. It is eminently desirable, then, in all cases, to ascertain distinctly what kind of a case you have to deal with. The occupation is scarcely less important, for if a city man, the ranges of food, through the middle of the day at least, is restricted to the viands of restaurants, most of which are unsuitable to a dyspeptic. Or the patient is connected with a large house of business and must take

"what is going," that is, what is provided for the inmates generally. In these last two cases the dietary becomes the difficulty.

Having cleared the case of all such elements, and formed a fair conception of what its surroundings are, the indigestion may be approached directly. The first matter is to ascertain what amount of pain is produced by the digestive act, its time in the digestive process, and whether or not much flatulence is coexistent. When an ulcer is present the pain is set up almost synchronously with the introduction of food into the stomach, as soon as the contents become acid from the flow of the acid gastric juice. Here the line to be taken is clearly that of trying to put gastric action in abeyance and trust to the pancreas. Milk sheathed with an alkali, with or without some biscuit powder, will probably pass readily through the stomach without producing much suffering, and be digested successfully in the intestine, and in order to save the stomach the patient may be fed per rectum to a considerable extent for a time. Physiological rest so being afforded to the stomach the healing of the ulcer is favored and, in many cases, is readily accomplished.

In other cases the pain is not experienced until we believe the food is passing through the pyloric ring, and intestinal digestion is being inaugurated. What do we do in such a case? There are two lines open to us which may be combined in practice: (1) we may try what can be done by suitable food and some pepsin, to secure complete disintegration of the contents of the stomach so that they shall not irritate the duodenum; (2) we may stimulate the action of the liver and give liquor pancreaticus. And by such measures we can probably do the patient a great deal of good. At the same time, a sufficient time must be given to the taking of food; while the patient should be relieved from worry, as by leaving his or her business or occupation for a time, thus giving the medicinal treatment a fair chance.

And now a few words may be said about the resort to artificial digestive agents. Of the extreme value of these agents in strengthening our hands when dealing with indigestion there can be no two opinions, and Dr. William Roberts, F.R.S., ought to be held in affectionate remembrance by every dyspeptic, both those who require these agents actually and those who might come to require them.

But it seems to me, from a recent experience, the tendency is to resort to these agents at once, instead of encouraging the natural efforts and holding the artificial agents in reserve. For instance, a few days ago a youth came up from the midlands, who had been put upon artificially digested milk and milk porridge, but with whom no attempt had been made to foster the digestive act. To such artificially digested food had been added phosphorus and strychnine, while nothing had been done to secure proper action of the bowels. On explaining that the line which suggested itself to me was that of encouraging the natural processes, instead of doing the work for them, the father of the patient, a farmer familiar with the varied outcomes of pauperism, showed his comprehension of what I was driving at by remarking, "Not to make a pauper of his stomach, Doctor, eh?" which meant that the stomach was weakened by having its work done for it. Now this was precisely my own view in familiar phrase. In such cases, the proper practice, in my opinion, is to encourage the natural powers, giving such food as shall least tax them. This is a good line to take; and

then if the case does not move forward, to give some artificially digested food, once, or perhaps twice a day (in order to nourish the body); pursuing the old line at the same time. But if this resort to artificially digested food were forced upon me, I should regard it as indicating a reduction of the body expenditure to the minimum. The patient ought to be sent to bed. Warm in bed, the need for hydrocarbons is small; at rest the tissues require little repair. In bed the amount of food required for the body needs is much less than when up and about. A patient remarked to me some time ago, "I can't eat enough to feed me properly, and if I did I could not digest it!" What was to be done? He was sent to bed, and then "the body expenditure" fell below "the body income" and the surplus went to add to the body weight.

What are our means of encouraging the natural powers? First the digestive act in the gastro-intestinal canal, and secondly in the liver. And this involves the question, What is it which needs improving, the assimilation of hydro-carbons or the assimilation of albuminoids, or both? This is a matter too little insisted upon. Too commonly, action is taken rather blindly, and malt-extract (diastase), or pepsin, or pancreatic preparations prescribed without that discrimination which is so desirable. My own rule, so far as it is formulated, and it needs some corroboration (possibly some correction), is taking the following direction: When the patient is spare and too thin, then starch and sugar are indicated; and diastase should be added to farinaceous matters. Surplus sugar is laid down in the body as fat—i.e., within the storing capacity of the organism. Then when there is any tendency to glandular degeneration, and that growth of lowly connective tissue spoken of commonly as tubercle, the indication is some fat which can be assimilated, of which cream, butter, and cod-liver oil are the most digestible forms. When it is desirable to increase the power of assimilating fat, there are several measures which may be adopted, singly or together. There are agents which stimulate the flow of bile, which emulsionizes fat so that the pancreatic secretion may further act upon it, and the most useful of these is ipecacuanha. Ether has been found to stimulate the flow from the pancreas and so aid materially in the assimilation of fat. It might be given with liquor pancreaticus and cod-liver oil. Sometimes when cod-liver oil is not assimilated, it is well to resort to the following plan. The oil is observed unchanged in the stools, *en masse*, never having been divided into an emulsion. Here it is well to remember that a fatty acid helps in the emulsionizing of fat. So give some castile soap, say two grains, with two grains of dried ox-gall, in a pill, about two hours after a meal, when the contents of the stomach are passing into the duodenum. The fatty acid and the bile assist the natural efforts, and then the assimilation of fat is often materially aided.

At other times the liquor pancreaticus, guarded with an alkali (which may be potash or magnesia, and not necessarily the nauseous bicarbonates of soda), given as Dr. Roberts directs, is of great service. Probably all the constituents of our food—starch, albuminoids, and fats—are digested by this agent. Or some of the compounds containing several, or, indeed, all of the digestive agents may be used with success. If the medium is acid then pepsin is efficient; if the medium is alkaline, then the diastase and the pancreatic ferments are effective.

In very acute conditions it may become necessary to give milk and milk-gruel, already largely digested by the addition of liquor-pancreaticus; or these may be given at times, with ordinary milk and seltzer-water, or lime-water at other times in the day. Such are conditions where there is much gastric irritability with vomiting, and a tongue denuded of epithelium, or seen to be covered by a growth of young epithelium. This condition is not uncommon in the course of phthisis, and when it shows itself it requires its own peculiar treatment, all others being abandoned, for the time at least. Here the

line to be taken is that of alkalies and bismuth, with or without some hydrocyanic acid. Whenever the tongue is raw or bare, then alkalies are to be given, and acids carefully eschewed. If the reader has doubts about the last, let him just try the experiment with his eyes open, and watch it. It will not be long before the results will be apparent to him. Bismuth with soda in calumba is the old and well-known combination for such state; and with it the milk dietary just described may be combined. More commonly, however, a less grave and acute condition is found, where the state of the tongue is just the opposite, viz., covered with a layer of dead epithelium. Here acids are not only unobjectionable but are very useful. Indeed, soda sulphate with some acid is the combination which gives the most satisfactory results. Under this the tongue soon cleans, the appetite returns, and the stools are of a normal color. When the primæ viæ are once more acting normally and in a healthy state, then, and not till then, may some chalybeate be given. But as long as the liver is in any way disturbed, chalybeates are useless, and usually disagree. When the appropriate time comes, then iron is useful; but however impatiently the time is awaited, it is well to be patient. To resort to iron prematurely is a very common mistake. Sometimes when the tongue is placed in a side light, a yellow shade can be detected, and so long as that remains so long must chalybeates be withheld.

It is necessary in all cases to keep the bowels open. There is no treating indigestion satisfactorily so long as the bowels are loaded with fæces. The bowels must be swept out freely, and then kept open; and, if necessary, a sharp purgative must be given from time to time. Especially is this necessary with female patients, who dislike being purged (as it pulls them down), and who are very liable to allow themselves to become constipated. The reader, perhaps, thinks it quite unnecessary for me to insist on the bowels being kept properly open. But it so happens that to find patients, who have been under very judicious treatment in every other respect, but whose bowels have not been attended to, is far from an infrequent occurrence. Either the medical man has paid too slight attention to the matter, or the patient has failed to carry out the orders, or, may be, both. Anyhow, the fact remains, and so does the indigestion for that matter, and the case is truly incurable until this is rectified. It is easily done, as a rule, by adding the requisite dose of laxative to the pill I am about to describe. It is well, however, to keep short of purgation, else the pill is abandoned, and its other effects lost. So keep on the short side a little, and let the patient take some laxative water the first thing in the morning, if indicated. But a good many patients dislike this water in the morning, and then it is well to prescribe two pill forms, one more sharply laxative than the other, and let the patients take one of each daily, or otherwise vary them according to their requirements. This does not give much trouble, and that is a matter agreeable and acceptable to the patient. Pills can be kept out of sight, and people, as a rule, object to be regarded as invalids. Besides, no little matter, pills are tasteless, and when the medicine has to be continued for weeks or months, if that medicine be nauseous the patient conceives a mortal repugnance to it.

When the symptoms of acute discomfort show themselves during and after a meal, then a dose of pepsin often makes matters comfortable (McKesson & Robbins' pepsin pill is most convenient), or a second may be indicated if the meal contain much meat. Such immediate measure is excellent, while the following pill is taken before meals, steadily and continuously. There are many hepatic stimulants, as mercury, arsenic, eunymmin, baptisin, iridin, leptandrin, etc. But it may be questioned if any of them is so efficacious as ipecacuanha. A century of experience tells of the utility of ipecacuan in indigestion. It was a constituent of the dinner-pill of the last century. Not only does it stimulate the liver, and so be useful in cases of indigestion

where there is either bile acids formed in excess or lithates present (that is, the peptones which find their way into the portal vein from the intestinal canal and which, converted into proteids, are elaborated into the albumen of the liquor sanguinis by the liver normally, are transformed instead into bile acids or urates; the patient loses flesh, and on a flesh dietary only makes more bile or more lithates, without gaining weight), but ipecacuan is a "pepsin-persuader" from its action on the gastric lining membrane with its multitudinous glands and follicles. Ipecacuan combines properties, indeed, as does no other agent, in my opinion. Then there is often atony, either general or in the bowel, and for this strychnia is an admirable remedy. Perhaps, too, flatulence, for which a carminative is indicated. Then there is the vehicle, which may or may not be a laxative, according to the case. The pill would stand then somewhat as follows:

R. Strychniæ..... gr. $\frac{1}{30}$
 Pulv. ipecacuan..... gr. $\frac{2}{3}$
 Pulv. piper. nig..... gr. jss.
 Ext. gentian..... gr. j.

Yes, there it is! How familiar it does look; and what a lot of my patients are taking that pill with Pil. al. et myrrh., or Pil. coloc. co., according to their necessities! Once or twice a day before meals steadily followed out for weeks, with a pepsin pill, or maybe two, at dinner or other substantial meal, and a regulated dietary of farinaceous matter with milk. Steam-cooked cereals with milk, and a little fish or fat bacon to follow for breakfast. Lunch, a biscuit and milk, or a milk-pudding (made *without* an egg), with some stewed fruit, with a glass of wine. Then a walk before lunch and a rest on the sofa after. For dinner, some white meat with the milk-pudding and a glass of wine, with pleasant cheerful society. Perhaps, if the patient be hungry in the night, some milk and malt extract, gently warmed and kept under a cosy (which both keeps it warm and untainted by the air of the bedroom), to be taken in the small hours of the morning. A bracing locality and freedom from toil and worry.

This is about what I generally advise, and it seems to suit the patients, or else they tell me falsehoods and pay their fees in vain. Such, indeed, is the broad plan with dyspeptics suffering from inability to digest their food. Only the measures are to be fitted together in each case, as Opie mixed his colors—with brains!

A SERIES OF TWELVE OVARIOTOMIES.

By MATTHEW D. MANN, A.M., M.D.,

PROFESSOR OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF BUFFALO; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY.

OVARIOTOMY has become so common that one is almost forced to make excuses for publishing a case or even a series of cases unless they mount up into the hundreds. Although the various steps of this operation are now nearly settled, there are some points still in dispute. These can only be decided by experience, not only of each operator for himself, but by the careful study of the results obtained by others, and it is to this end that I make this report.

The twelve cases were, with the exception of the first, operated upon within the space of fifteen months. Of these nine recovered and three died; of those which died, the first (No. 5) was almost moribund when the operation was begun. Her pulse was 140 and temperature 103°. She had had suppuration of the cyst for a number of months and the cyst contents were very fetid and contained gas. She had been tapped three times, the pus, however, antedating the first tapping, and there was a small fistula opening into the abdominal cavity which emitted a clear fluid and at times gas and pus. The sac was attached over nearly the whole abdominal parietes and was so decomposed that in separating the adhesions it tore and let some of the contents into the abdominal

cavity. This was carefully washed and sponged out and a glass drainage-tube introduced. She rallied for the first twenty-four hours, but soon the temperature rose and she passed into a condition of violent mania and died forty-eight hours after the operation. She was operated upon at her home in the country and I saw her but once afterward.

The second fatal case (No. 6) was a cyst of the broad ligament, I diagnosed the probable nature of the tumor by tapping before operating, but decided to operate as the cyst seemed thick and very tense, and the patient was eager for relief and the diagnosis at best uncertain. The contents were like spring water and contained only a slight trace of albumen. The operation was very simple, there were no adhesions and no blood lost. The incision was very short and the pedicle long and the tumor was removed without disturbing either ovary. Everything was so favorable that there seemed to be no possible way in which a bad result could occur. She did splendidly for the first week and then developed symptoms of septic peritonitis and died on the twelfth day.

The cause of death in this case I cannot but attribute to hospitalism. She was operated on in the Buffalo General Hospital; she had a private room and nurse, but in the same building, about the same time, there had been several cases of septic disease (puerperal fever, etc.). I can see no other reasonable explanation of the cause of death. No blame can be attached to the hospital or its management, for no general hospital is, or ever can be, a proper place for abdominal surgery. I find it recorded that out of one hundred and forty-two cases operated on in four of the leading London hospitals, there was an average mortality of sixty per cent., while in two hundred and ninety-six cases the same year at the Samaritan Hospital, a small special hospital, under Mr. Spencer Wells, the mortality was only twenty-two per cent. A certain allowance must be made for the special skill of the one operator, but this alone could hardly account for the great disparity in results.

In justification of this operation as against tapping, I will say that the cyst when emptied weighed over three pounds and would undoubtedly have refilled; moreover, the diagnosis of cysts of the ligament by the peculiar character of the fluid has been shown to be unreliable.

The lesson taught by this case was still further enforced by the next (No. 7). This was in every way promising, no adhesions of any moment and the patient's general condition was good. The earlier period of convalescence was very favorable; the temperature remained nearly normal and the pulse generally below ninety, until the eighth day; she then had a slight chill; vomited several times, and felt very weak and uncomfortable, the temperature fell to 97 and the pulse went to 118; from this time on she steadily failed. The temperature kept near the normal line, sometimes below, but the pulse went to 110-120 and diarrhoea set in. Transfusion was tried, Dr. Long of this city generously furnishing the blood, and Dr. Charles Cary, who has had considerable experience in this procedure, kindly lent me his aid and superintended the operation. The operation was by the mediate method. The blood was withdrawn from the arm of the donor by an aspirator and forced into the arm of the patient without allowing it to come in contact with the air. In this way it was only a few seconds out of the veins. The canule of an Aveling's apparatus were introduced into the veins of both parties before the aspirator was attached. The effect of the transfusion was but transitory and she died exhausted on the fourteenth day after the ovariectomy. There was no pain but the vomiting kept up and the large dejections were persistent. The mental faculties were unaffected.

The autopsy did not throw much light on the cause or nature of the disease. There were a few ounces of blood, serum in the abdominal cavity, and several feet of the small intestine were as black as ink. There were also spots of discoloration on the stomach and large intestine. Nothing else wrong. Union of the wound complete; no

clots and no evidence of peritonitis. I cannot but think that the trouble was septic in its origin, and attribute it to the same cause as the other, but the symptoms were not those we generally associate with septicæmia. However this may be, it served to impress most forcibly on my mind the fact that a general hospital, no matter how well cared for, is no place for ovariectomy.

The point has been made that double ovariectomy is more dangerous than where only one ovary is removed. In three of these cases (Nos. 2, 3, and 8) I removed both ovaries and all recovered. In No. 8 the supravaginal portion of the uterus was also removed. An interesting point in this latter case is that this patient, although she survived the removal first of a fibrous polypus from the cervix and then of double ovarian tumors with the uterus, is now about to succumb to cancer in the vagina.

It will be noticed that Case 9 had reached the great age of seventy-seven years. It is generally thought that such an age is a contra-indication to an operation, but statistics do not support this idea. In the last edition of his work on ovarian tumors (1882), Sir Spencer Wells, in speaking of the results in this operation as modified by the age of the patient, says: "The small mortality shown in patients below the age of twenty-five and above the age of sixty, and the comparatively high mortality between those ages, except from forty to forty-five, are remarkable." The number of cases on which he bases his percentage of mortality between sixty and seventy years of age is forty-five, with thirty-seven recoveries (eighty-two per cent.), while above seventy he has had but two cases, one of which recovered at seventy-seven. In 1853 Atlee reported a case aged seventy-eight, in which the operation was successful. Thus we have four cases with three recoveries. My patient seemed to be in perfect health, aside from the tumor, and was very anxious for relief. The tumor had been growing only eighteen months and had reached a great size. I could see no good reason for not operating and the result justified this view. Although the operation was rather severe and long (an hour and a half), owing to the difficulty of securing all bleeding points, she stood it well and made a rapid recovery.

In the earlier cases I used the drainage-tube for a slight indication, but I found so much annoyance from its use and so much difficulty in closing the sinus left by it, that I discarded it after the fifth case. Still I can readily imagine a case where its use might be unavoidable. In Case 4 there was considerable ascitic fluid outside the tumor, and I should be inclined to consider this a good reason for the employment of a tube. A large oozing surface after an enucleation, as in Case 2, would also be an indication, and its use in this case, I have no doubt, had a large influence in promoting the recovery. I have used the simple glass-tube, slightly curved, and carried to the bottom of the cul-de-sac.

The method of treating the pedicle is now so nearly settled that but little need be said about it. I have always tied and then severed the tissues, either with scissors or latterly with the thermo-cautery. For ligatures I have used the raw silk well carbolized. That the silk is absorbed I do not believe, as I have once or twice seen silk which had remained in the abdomen for a long time unaltered. For adhesions, I either divide with the cautery alone or tie first; if the tissues are very vascular, with catgut, or if they are very large, with silk.

The length of the incision I have never considered as having much influence on the result. Operations in which the incisions are long will always make a worse showing than those with short incisions, but the reason is not in the length of the incision but in the conditions which make the long incision necessary. My rule has been to begin with a short incision and to enlarge it as much as necessary as I proceed.

An article of this kind at this time would not be complete without some words about antiseptics. I began with antiseptics, spray and all, and my first case was done under the carbolic spray. But soon after this I lost a case of oöphorectomy (*American Journal of Obstetrics*, October, 1880) from what I believe to have been carbolic poisoning. This made me afraid of carbolic acid, and I dropped the spray for a time. After I had lost three cases in succession, I began to inquire very carefully for the cause, and thinking that perhaps the use of the spray would better my results I began it again, using, however, boroglyceride (1-20) rather than carbolic acid. The last five cases were done under this spray, and as all recovered I am inclined to attribute something of the result to its use. There is one symptom which sometimes follows it and which I have seen noted elsewhere, which is very alarming unless its cause is understood. In Case 11 the pulse and temperature remained normal, but there was a very unaccountable and marked dryness of the tongue and mouth. This continued, not-

withstanding brandy, potas. chlorat., etc., and ceased suddenly on the third day. That it was due to the boroglyceride I am sure, as others have noticed the same thing after its use. For hands, instruments, ligatures, and sponges, I have used carbolic acid, and as a dressing boroglyceride cotton held in place by a flannel bandage, rather than adhesive straps.

The preparatory treatment has been the simplest possible, a thorough cleansing of the bowels and a bath, nothing more. To dose a patient with quinine and opium, and thus upset the stomach and disturb the nervous system just when a great call is about to be made on them, always seemed to me to be unphysiological and irrational. The after-treatment has likewise been simple, opium in some form enough to quiet all pain and restlessness, but no more than is absolutely required. Brandy and ice, *if indicated*, not as a routine practice, milk and food as soon as the patient wants it, generally on the second day, at first in small quantities every two or three hours. The bowels are moved on the seventh or eighth day, as soon as the stitches are out, by a simple laxative and enema.

The results have not been as good as some operators, notably in England, have obtained; but the reasons for the failure in the fatal cases have, I think, been clearly given.

MASTOID DISEASE—ARTIFICIAL PERFORATION OF THE BONE—TEMPORARY RELIEF—DEATH FROM PYÆMIA.

By CHARLES H. BURNETT, M.D.,

PHILADELPHIA, PA.

THIS paper contains an account of a case of chronic purulent inflammation of the middle ear, inducing general increased vascularity of the pyramidal part of the temporal bone, hyperostosis of the outer wall of the mastoid portion, and a thinning of the sigmoid groove, without necrosis. The mastoid cavity became filled with cheesy debris, and this furnishing a pyæmic source, embolism of a chronic form ensued, as shown first by the abscess in the lung and then by the pyæmic infiltration of the liver resulting in a vast number of abscesses. The operation, it will be seen, gave temporary relief to the acute aural and mastoid symptoms, but, of course, had no effect upon the pyæmic element in the case, because of the great chronicity in this latter respect. An early operation, perhaps years before, might have prevented the accumulation of cheesy masses in the mastoid antrum and the consequent occurrence of pyæmia.

History.—James B.—; thirty years old; born in Ireland; a weaver, was admitted to the Presbyterian Hospital, Philadelphia, April 11, 1877. His aspect was phthisical but he stated that his health had always been good until within ten weeks, when he was admitted to a hospital for "pleurisy." He remained there seven weeks, when he was dismissed cured, as he was told. Immediately following his sojourn in the aforesaid hospital his right ear became painful and sore to the touch, the auricle stood out from the head and the pain in and about the ear was so great as to deprive him of sleep. After enduring this suffering for two weeks he was admitted to the Presbyterian Hospital, where I examined him, and obtained the above history, on April 13, 1877. At this time his right auricle was standing far out from the head, the mastoid region was red, boggy, and tender on hard and deep pressure. His pain was chiefly and constantly in the mastoid; but at times there was a dart of pain into the right temple. An offensive, thin, transparent yellowish matter flowed copiously from the painful ear, and examination revealed a largely perforated membrana tympani and a macerated and tender auditory canal with granulations on the posterior wall. The watch could be heard only in contact. The patient stated that this ear had been affected for many years with discharge and that at times he had attacks of pain and soreness similar to this, but that no attack had been as severe as

this last one. His pulse was 88; appetite good; secretions normal, no cerebral symptoms. Four leeches were now applied to the mastoid region and four or five ounces of blood were drawn. This gave but slight relief, and at bedtime, a few hours later, he was obliged to have one-eighth grain morphia sulph. to get rest. He awoke from time to time with pain, and obtained some ease with two-eighths grain more of morphia.

April 14th.—The next morning his face was flushed; pain in mastoid very severe; pulse, 86; temperature, 98 $\frac{3}{4}$; tongue coated; headache and malaise great. Afternoon: pain increasing in the mastoid; latter very tender, especially at its tip; appetite fair; bowels open; no cerebral symptoms. At four P.M. the patient was etherized, and after making an incision in the soft parts one-fourth inch behind the auricle, I perforated the outer mastoid wall with S. H. Buck's conical drill, three-fourths of an inch above the tip of the process. The severed branch of the posterior auricular artery was ligated. No pus issued from the opening thus made in the bone, but the cellular structure of the mastoid was easily reached through this opening and the cells toward the antrum were broken by a probe, thus affording an exit for retained pus. The periosteum was dissected freely from the mastoid but no disease of the outer table of the bone was found. A simple greased tent was now put into the wound thus made and the patient put to bed to await recovery from the ether narcosis. Beef-tea and milk ordered, and morphia if pain continues.

April 15th.—Appetite good; pain generally less, though the neck was sore and stiff, probably from bruising at operation. Mastoid incision suppurating and mastoid tip tender. Some frontal headache, but the great pain in the temple and the mastoid had gone.

April 16th.—I ordered six grains quinine daily; tent removed and poultices placed over the mastoid opening. Pus issues from the artificial opening in the bone. Patient sits up in bed and looks and feels much better. Has had no cerebral symptoms.

April 17th.—Ligature from artery comes away; patient comfortable.

April 18th.—Some fever this morning, with photophobia and intolerance of all sounds. One-eighth grain morphia at night.

April 19th.—Patient appearing weak and sleepless, gets a milk-punch every three hours, and quin. sulph., gr. ijss., every four hours, with morph. sulph., gr. $\frac{1}{8}$, two or three times in the night.

April 20th.—This morning has less fever and less pain; discharge free and purulent, from mastoid opening and from the meatus. Urine contains no albumen.

April 21st.—Less fever and no pain; discharge from wound diminishing.

April 22d-23d.—Appears to be getting well; wound in mastoid healing.

April 24th.—Ten days after operation is able to get up and dress himself and walk about the ward; stimulants stopped. In the evening began to complain of general malaise; his temperature rose and his pulse became more frequent; tongue dry.

April 25th.—Remains in bed; whiskey and quinine resumed, pulse full and bounding; temperature, 104.6°; bowels confined; whiskey stopped and a fever mixture given; wakeful and nauseated all night.

April 26th.—Tongue dry and brownish; constant nausea and vomiting; *complains of pain in region of the liver.* Violent chill in afternoon. Is taking brandy and soda, and two and a half grains quinine every three hours.

April 27th.—Tongue is better, but still complains of nausea and pain in stomach and over the liver; fever continues. Discharge from the wound and ear less, very little pain and soreness in mastoid, wound nearly healed.

April 28th.—Bowels inclined to be relaxed through the night. Temperature, 104°; delirious during night.

April 29th.—Tongue dry and brown; pain and tenderness in hepatic region great. Hiccough, vomiting, and delirium. Pulse more rapid and weaker; respirations very rapid; coma. Death at 1.30 A.M. on April 30th.

Post-mortem examination, fifteen hours after death.—The omentum in proper position, but darkened by venous congestion and at its upper and right hand side thickly studded with flakes of recent lymph. The stomach was marked externally by patches of lymph over the fundus and at its pyloric end was adherent to the under surface of the liver. The duodenum firmly adherent to contiguous viscera and so softened as to be torn in attempting to remove it. The liver was covered externally with peripheral abscesses, like yellow spots, varying from one-fourth of an inch to one inch in diameter. The spleen contained no abscesses. The liver was found filled with disseminated abscesses throughout its parenchyma. The left lung was normal excepting the presence of small abscess on outer side of lower lobe, one-half inch in diameter, surrounded by hardened zone, the whole one to one and one-half inch in diameter. Brain: The cerebral surface of the temporal bone of the diseased side was slightly darker than its fellow, and the dura mater not so adherent as on the normal side. The tympanic cavity and mastoid cells were filled with a cheesy mass; the ossicles were present; membrana tympani largely destroyed. There was great hyperostosis of the outer table of the mastoid portion; it was half an inch thick at a point three-fourths of an inch behind the external auditory meatus. There was no necrosis of any part of the temporal bone; no sign of phlebitis, nor of thrombosis in the sinuses of the brain, nor in any of the veins leading from the tympanum. The cheesy mass in the mastoid cells was lying against the mastoid surface of the bony gutter in which runs the lateral sinus, but there was no necrotic spot in this bony channel. Numerous evidences of extensive chronic disease in the temporal bone were found, consisting in the great thickening of the outer wall of the mastoid, as stated already, and in a thinning of its inner wall where in contact with the sigmoid sinus. The nutrient vessels and the canals conveying them in this region of the temporal bone were much wider and larger than on the healthy side. It seems highly probable that the embolism occurred by the way of the lateral sinus, in consequence of the morbid changes in that region, just narrated.

Conclusions.—1. This man died of pyæmia induced by long continued purulent disease in the middle ear and mastoid cavity. The embolic elements passed by the brain to lodge in the lung and liver, an unusual course in pyæmia from ear disease. 2. The operation of trephining or perforation of the outer mastoid table is strongly indicated in such cases. It has no effect whatever in hastening a fatal issue, even if it had no effect in preventing it, as shown in this case, as the man recovered from the operation to die of pyæmia. 3. When fistulous openings exist in the upper back part of the bony auditory canal, as in this case, it becomes worthy of our consideration whether we should not follow the indication of nature and make a larger opening at such a point, especially as we may in such cases suspect hyperostosis of the outer wall of the mastoid. 4. The safety of the operation on one side, and the great dangers of a concealed pyæmic nidus in the mastoid, in chronic purulent otitis media, on the other hand, should incline us to regard, in many cases, a prompt opening of the mastoid wall as the one great chance of saving the patient's life.

HOW TO GET BACK?—A correspondent from the dispensary department of the New York Infirmary for Women and Children reports an individual of the *Cimex lectularius*, or common bed-bug, found perched upon the external os of the cervix uteri in an abundant vaginal catarrh. The insect was removed and was unmistakably identified.

A FATAL CASE OF TYPHLITIS WITHOUT RECOGNIZABLE SYMPTOMS.

By JOSÉ M. FERRER, M.D.,

NEW YORK.

THE desire to contribute, however slightly, to the general fund of information on the subject, together with certain features of practical interest, must form my apology for putting the following case on record.

S. J. M.—was a stout, healthy girl, nineteen years of age. Despite a history of phthisis on both sides of the family, no constitutional taint of weakness marred her perfect physiological life. Aside from rubeola and a few trifling ailments in her earlier life, she had never been sick.

I was called to see the patient about midnight on Saturday, June 2, 1883. She had been visiting her friends all day, and on her return home nothing unusual was noticed, except that she complained of slight headache and of being tired out. At 6 P.M. she ate no dinner and seemed exceptionally quiet. After dinner she laid down on the lounge, and, as I learned after her death, called for a blanket, saying she felt cool, as the windows were open, the evening being warm. About 8.30 P.M. she commenced to vomit, at first but sparingly, and almost simultaneously she was taken with a *severe pain in the epigastric region*, which she localized by placing her hand on the "pit of her stomach." The vomited matters were almost entirely bilious. There seemed to be reflex irritation of the rectum, for she tried to go to stool twice, passing very little. Palpation and percussion of the abdomen revealed nothing special. The pain seemed to abate somewhat after one drachm of the U. S. solution of morphia, and there was no vomiting for about an hour. Later, another drachm was administered, but was vomited almost immediately. Despite counter-irritation of the abdomen, emesis continued at intervals. When I left her she seemed more quiet, the symptoms abating. A warm poultice was applied and she fell into a doze.

Sunday, June 3d.—I called about 9 A.M. and found the patient more comfortable. She complained of *soreness about the epigastrium*, but said she did not have the pain like the previous evening. The sore and tired feeling were attributed to her continued efforts at vomiting. I asked about the menses and she said they were "all right." I asked if she had any pain down the bottom of the abdomen, and she said no. I again palpated the abdomen all over but discovered nothing, and caused some discomfort. No tympanites; no signs of a hernia. Pulse, 90. Temperature not taken, as there was no thermometer at hand, but there was evidently no fever. Auscultation of the chest with negative results. She did not give indication of being very sick. She insisted on sitting in a chair by her bed for a while, and walked across the room two or three times to the *pôt de chambre*. Through the day she vomited considerable quantities of bile, and some teaspoonfuls of beef-tea which she had taken. In the evening her temperature was 38½° C., and pulse 90 to 100. She looked pretty well, and, ordering a sponge-bath and a large poultice, which she kept on all night, I left her.

Monday, June 4th.—I saw the patient about 9.30 A.M. She seemed in good condition. Had slept part of the night. Temperature, 100° F.; pulse, 90. She still complained of some soreness of the abdomen but no pain, and more like a sense of weight; she said, "It feels so heavy." All vomiting had ceased. She sat in a chair for a while, and did not seem to desire absolute rest. She received some friends in her room that afternoon and spoke cheerfully with them. When in bed she lay covered with a blanket and coverlet. Her cheeks now became flushed and she had much thirst. In the evening when I called her temperature was 103° F., and pulse, 120. This was the highest record at any time and occurred only on this one evening. Vomiting not present;

pain not spoken of. *No tympanites.* Lips parched and face flushed; urine high colored. She seemed somewhat apprehensive, and wanted me near her, but appeared at the same time good-natured, and even smiled. Fearing to induce vomiting anew, no quinine was ordered. Only sponge-baths and cold lemonade when she should want it.

Tuesday, June 5th.—At 9.30 A.M. temperature had gone down to $100\frac{1}{2}^{\circ}$ F. and pulse to 100. The flush had faded from the face. Emesis had not recurred. The sense of weight was only referred to on repeated questioning. The respirations began now to be quickened, thoracic, and not deep. No morbid signs in the chest. Condition remained about the same through the day, with same range of temperature, and pulse varying from 100 to 110. The lips were parched and glossy. In the afternoon she commenced to have a clammy perspiration, and the extremities were cool. In the afternoon, also, tympanites developed, but moderate only, and flatus was voided, later there was some hiccough and the respirations continued quick. With all this, her condition did not manifest the imminent peril in which she was. She walked from her bed to another room. In this room she walked from the bed to a chair across and sat down, after a while she moved again to a lounge; and, though not talkative, followed the conversation and answered opportunely. She no longer mentioned the pain or soreness. There had been no vomiting that day or the day before. That evening the temperature was, as in the morning, $100\frac{1}{2}^{\circ}$ F., and pulse 110 and weak, respirations about 30. The room was close and warm. She tossed about in bed a great deal. I left her at 10 P.M., as she said she was going to sleep, and asked me to call early in the morning, she was then bathed in a cool sweat, but seemed in fair condition. During the night she had three movements, passing a very small amount of feces highly colored with bile. She had refused all nourishment.

I was summoned hastily at about 3 A.M. on Wednesday, June 6th, and found the patient going rapidly into collapse. Once previous to my coming, and twice subsequently, she vomited large quantities of dark-brownish pseudo-stercoraceous matter. She had hiccough, cold extremities, small pulse, and other signs of collapse. Dr. Satterlee was called in consultation, but there was little to be done at such an hour. It was evident she was *in articulo mortis*. She complained of vertigo, the bed's turning around, etc.; she began to wander and soon became unconscious. Despite active stimulation, she died in collapse at 4.30 A.M.

Post-mortem examination, by Professor Delafield, eight hours after death, Dr. Satterlee and myself being present. The body was well nourished and external inspection revealed nothing special. Rigor mortis present. Only the abdominal cavity was examined. The evidences of a general acute peritonitis were discovered at once. The stage was an early one, the bright arborescent condition of the vessels being still preserved. There were some delicate fibrinous adhesions forming. At the bottom of the abdominal cavity there were probably two ounces of purulent serum. The intestines were full of gas.

On pulling up the cæcum into view, the vermiform appendix was discovered free in the abdominal cavity, and acutely inflamed. It was increased in size to probably four times its original diameter, and was about four inches long. It felt hard to the touch, and remained erect. Its posterior and interior aspect presented a yellowish, sloughy appearance. Here, then, was the original cause of the trouble. Further inspection revealed a small mass of hardened feces, about the size of a small bean, as the foreign body. There was no perforation proper, but the walls of the appendix were softened and infiltrated with pus.

Remarks.—There are several aspects of the case that merit consideration and study.

To commence with the *etiology*. Here was "a small mass of hardened feces about the size of a small bean" impacted in the vermiform appendix. Examination failed to discover any foreign nucleus to this mass. Its own consistent hardness was sufficient to strangulate the appendix, or at least to cause a most marked inflammation thereof.

Now, in the healthy subject fecal matters find their way in and out of the appendix without inconvenience. And for a purely fecal mass of sufficient hardness to cause an acute inflammation, we would predicate marked constipation, particularly if we excluded the possibility of the little mass hardening *in situ* without causing previous symptoms. Such, indeed, is the view held by all writers on the subject. To quote one: "Most frequently," says Bauer ("Ziemss. Cyclop.," art., "Infl. Proc. in the Right Il. Possa."), "we meet with irregularities of the bowels; either constipation has existed for a long time, or this has alternated with diarrhoea, until finally obstinate constipation has become established." "It is true," Bristowe says ("Reynolds' Syst. of Med.," art., "Dis. of Cæc. and App. Verm."), that "the concretions . . . consist obviously of the admixture, in unequal proportions, of ordinary fecal matters, and of the secretions from the mucous membrane of the appendix, and have obviously formed in the situation in which they are found, either round a nucleus of solid matter which has been first precipitated and concreted there, or round some comparatively small body of extraneous origin." Here we find no direct allusion to constipation as a primary cause, but it is fair to conclude that the inference flows from the well-known fact that "one of the physiological phenomena of this portion of intestine is that its contents become more solid and remain a long time in it," and that "there are a number of circumstances which may induce the contents to remain for a much longer period than usual, and in connection with this to become very hard" (Bauer, loc. cit.). Else, how explain the "nucleus of solid matter which has been first precipitated and concreted there?" Constipation, then, is presupposed when we do not deal with the impaction of extraneous bodies.

But, according to her own statement and that of her family, this girl did not suffer from constipation; and the slight amounts she passed during her short illness were of the ordinary pasty consistency, while the necropsy revealed the cæcum and colon remarkably free from feces. Was this particular bit of such hardness that the appendix could not get rid of it, as it does of other matters, it possessing normal tonicity, the girl being in perfect health? And if so, why should it have differed from the rest, which was voided naturally and seemed of ordinary consistency?

I can offer no explanation, and merely state the fact that, without a previous history of constipation, a little mass of hardened feces without a foreign nucleus was found impacted in the cæcal appendage, having caused it to become acutely inflamed, that an acute general peritonitis resulted therefrom, and the patient died.

The general process in the peritoneum was by extension, no perforation proper having occurred. After reciting several cases, Dr. Copland ("Dict. of Prac. Med.") says: "From the history of these and other cases, which have occurred to me and several of my medical friends, it may be inferred that inflammation, affecting primarily the cæcal appendage, is most frequently brought on by hard substances having escaped into it; and that the inflammation rapidly extends to the peritoneum, giving rise to the exudation of albuminous lymph, to adhesion of its opposite surfaces, and of the appendix to adjoining parts, and to gangrene of this process."

Finally, all authorities are agreed that typhlitis occurs much more frequently in males than in females. The foregoing case is offered to add to the statistical record of typhlitis in the female.

Clinical history.—It is in the history that we find peculiarities. And it bears out the experience which is

daily increasing and becoming more recognized, that a patient may appear to be but slightly ill while suffering from a fatal peritonitis.

Speaking of diseases of the cæcum and its appendage, Dr. John Burne says ("Royal Med. and Chir. Trans.," vol. xx.): "The diseases in question are, nevertheless, of frequent occurrence, are always dangerous, often fatal, and characterized by a train of symptoms so peculiar and marked as to render the recognition of them certain and not difficult." In view of the foregoing case, I would take issue with the last broad statement. For this girl gave absolutely no manifestations of typhlitis during life. Contrast the vivid picture given by Copland (loc. cit.)—who, according to Bartholow (*Amer. Jour. Med. Scienc.*, October, 1866, art., "Typhl. and Perityphl."), has written the best article on the subject, and which account is an exponent of the typical history, accepted as such by all practitioners—with the blank presented in this history. "Very acute pain," he says, "tumefaction, and tenderness are complained of upon the invasion of this form of the disease, first in the right iliac region, and subsequently more or less over the abdomen, with excruciating tormina, obstinate constipation of the bowels, a very frequent, small, or contracted pulse, heat of skin, dry tongue, great thirst, sometimes with numbness of the right leg, or pain shooting down the thigh, and retraction of the testicle. Vomiting comes on sooner or later, and is often, at one period or another, attended by the discharge of matters from the small intestines—at least in the cases I have seen. The patient at last becomes restless, his countenance sunk, and a fatal termination takes place, generally from the third to the sixth day, preceded by the symptoms ushering in dissolution from intestinal peritonitis."

Baner says (loc. cit.): "The diagnosis rests most prominently on the painful tumor in the region of the cæcum, and further, on the previously existing symptoms, and the symptoms of circumscribed peritonitis which are subsequently developed in connection with the tumor." Burne (loc. cit.) says practically the same thing.

In the present case there was no apparent constipation. Discomfort, pain, or tenderness were *never once* localized in the right iliac region. Even upon direct questioning, pain anywhere in the lower portion of the abdomen was denied. On the contrary, whenever she complained at all, even in the beginning, it was about the epigastric region, and never anywhere else. Palpation, often performed during her illness, revealed no local tenderness, but rather a generalized discomfort. Neither was a tumor of any description discovered. No such "painful tumor near the cæcum," as dwelt on by Flint ("Prac. of Med.") and described in Jackson's "Letters to a Young Physician," was present. And, moreover, the autopsy proved that none such could have been felt, there being no typhlitis stercoralis (accumulation of feces), the appendix being behind the cæcum, it being the only organ markedly enlarged, and there existing no salient perityphlitic deposit.

Now, in this case, again, there was no distinct positive history of peritonitis itself. With regard to the pain, we are taught to expect it as a rule, violent, continuous, increased by the slightest pressure, and relieved only by opium. Exquisite tenderness we count on. And our mind pictures the patient lying motionless on his back, with his knees drawn up, an anxious expression on the face; the slightest interference with the abdomen causing agony, even the weight of the bed-clothes being resented. Fever, with a temperature of 105° F., or more; pulse, 120 to 130. We look for tympanites early, and usually get vomiting. Great general prostration is the rule. Now, what did we have? Pain there was, but only in the beginning, and apparently localized about the stomach. It was not complained of for the last two days. "Sometimes," says Dr. Wardell ("Reynolds' Sys. of Med.," art. "Perit."), "that

cardinal symptom, pain, upon which such emphasis has been laid, only obtains at the outset; and notwithstanding its subsidence the malady goes on."

Tenderness and increased pain on pressure were not present to any great extent. Witness the number of times palpation and percussion were permitted, for the last time, on the eve of her death, and this with slight discomfort only. The abdominal muscles were not relaxed, and never did she lie with knees drawn up. She had a large poultice on all night and part of the next day, and was always covered with a blanket and coverlet which rested on the abdomen.

The pulse was 90 and thereabouts, except on the second evening and at the last, regular and of good quality. Wardell (loc. cit.) says: "The pulse is not always, however, a sure guide, as most serious attacks may be progressing under all conditions of the arterial circulation; and even pain on pressure—the most trustworthy of all individual symptoms—is not invariably to be relied upon, because it is not uniformly commensurate with the amount of lesion which really obtains."

The highest temperature occurred on the second evening, the thermometer marking 103° F., certainly not a high record for the intense and sthenic peritonitis discovered post-mortem.

Tympanites occurred only on the afternoon of the last day, and then not prominently.

For the last two days all vomiting had ceased.

But it is in the *tout-ensemble* of the disease-picture—the deportment, expression, prostration, etc.—which serves as an index to the laity, and which is of wondrous aid to the physician himself, that marked lines failed to convey the actual condition of the patient.

There was no Hippocratic countenance, only a relative degree of seriousness compatible with simple malaise. The patient did not seem to desire absolute rest. On the contrary, she moved about from the bed to the chamber, from bed to chair, from chair to lounge, from room to room, and this even until a few hours before death. She did not seem much prostrated, except at the last, and altogether her general condition did not indicate her impending dissolution. She was sick but three days and eight hours.

We may conclude with the words of Prof. Thomas ("Dis. of Wom.," fifth edition, p. 494): "With reference to general peritonitis, it may be stated that, on the one hand, it, of all diseases, may declare itself by the most numerous and characteristic symptoms, or, on the other, run its fearful course with the greatest obscurity, so as to mislead the most careful diagnostician, even up to its latest stages."

Prognosis.—Under the circumstances an uncertain prognosis only could be given, and there were not the elements for a fatal one till very late in the disease.

Treatment was entirely symptomatic. But it is more than doubtful that any treatment would have availed, the cause being not removable.

43 EAST THIRTIETH STREET.

THE TONGUE AT THE VAULT OF THE PHARYNX.—Dr. J. J. Buchanan, of Pittsburg, Pa., writes: "Three cases have been recently reported in THE RECORD of persons, who are able to explore the vault of the pharynx with the tip of the tongue. From the absence of any known record of similar cases the inference was drawn that such instances are rare. The following additional case has since come under the observation of the writer: W. M.—, male, student, about twenty-three years of age, in the course of a laryngeal examination developed the fact that he could easily pass his tongue behind the *velum palati*. He was able to outline the vault of the pharynx and the posterior nares and to move forward a probe passed along the floor of the nasal cavity. The frenum was poorly developed, but he could give no history of its section."

ON THE MANAGEMENT OF CASES OF IRITIS.¹

BY CHARLES J. KIPP, M.D.,

NEWARK, N. J.

IN the treatment of all of the different forms of iritis, from whatever cause, the chief indication is to secure complete dilatation of the pupil, and to maintain the same for some time after all inflammatory symptoms have disappeared. If the case is seen within a few days after the first symptoms have manifested themselves, a few drops of a one per cent. solution of the sulphate of atropine instilled four or five times in intervals of five minutes, will generally break up any adhesions which may have formed between the pupillary margin and the anterior capsule of the lens, and produce a widely dilated, round pupil. After this result has been obtained, the instillation need be repeated only sufficiently often to maintain the dilatation, which is usually accomplished by four to six instillations daily.

If, as is very rarely the case, the instillation of the sulphate of atropine produces symptoms of poisoning, such as redness of skin, dryness of mouth and fauces, great thirst, a quick and weak pulse, palpitation, headache, ischuria, etc., the passage of the atropine into the pharynx should, if possible, be prevented by pressing firmly on the lachrymal sac each time the drug is instilled, and if this is not successful in preventing the poisoning, some other mydriatic must be substituted. The sulphate of duboisine, the sulphate of hyoscyamine, daturine, or the hydro-bromate of homatropine may be used for this purpose. Of these the duboisine is probably most extensively used, as it is more certain in its action on the pupils than the others; but unfortunately it is apt to produce constitutional disturbance in the very cases which have an idiosyncrasy against atropine. Duboisine and hyoscyamine should be used in solution containing not more than two grains to the ounce. Homatropine I have used somewhat extensively in children, and have never seen symptoms of poisoning follow its use. Its effect on the pupil is, however, much more transient than either of the other mydriatics mentioned, and it is therefore necessary to repeat the instillation very often. I have generally employed it in one or two per cent. solutions.

The prolonged use of any one of the mydriatics here mentioned occasionally produces considerable irritation of the conjunctiva and inflammation of the integument of the lids. In some cases I have seen a well-marked follicular conjunctivitis and an inflammation of the skin of lids and cheek closely resembling erysipelas follow their use. In such cases it is best, if it can be safely done, to suspend the use of mydriatics altogether for a while, and to apply a one per cent. solution of nitrate of silver, or sulphate of zinc to the conjunctiva, and an ointment of the oxide of zinc, or the acetate of lead to the skin until the irritation has subsided, and then to resume the same or some other mydriatic. If all of the alkaloids mentioned cause irritation, a strong, well-filtered watery solution of the extract of belladonna may be substituted. Notwithstanding the disadvantages here mentioned of atropine, I think that on the whole it is to be preferred to all other mydriatics.

In cases of iritis of long standing, in which the tissue of the iris is swollen and infiltrated, and the pupil much contracted, the one per cent. solution of the sulphate of atropine, instilled in the manner described, will, however, not only occasionally fail to make much of an impression on the pupil, but will in some very rare cases even increase the irritability of the eye. Under such circumstances it is advisable to instil the atropine solution not more than five or six times daily, and to employ at the same time other measures to diminish the congestion and swelling of the iris. Of the various measures used for this purpose, none has, in my own hands, given

more satisfactory results than local abstraction of blood by means of four to eight leeches applied to the temple. In many of my cases in which, before the application of the leeches, atropine failed to act, complete or at least partial dilatation followed the leeching, and this took place often before the instillations were resumed. In localities where leeches are scarce, or in cases where it seems desirable to avoid the disfigurement resulting from the little scars, Fischer's plan of making a single leech do the work of many may be tried. It consists in making a long incision in the side of the leech after it has well filled itself. It is said that a leech thus treated will take from one to two ounces of blood if the wound in its side is kept free from clots. After the application of the leeches the patient should be kept in bed, or should at least remain quietly in a darkened room for twenty-four hours, or longer. If only slight improvement follows the leeching, it can, if necessary, be repeated several times, at intervals of several days. In cases in which the leeching is contra-indicated by marked anæmia, a considerable reduction in the congestion and the swelling of the iris is sometimes brought about by the action of a brisk cathartic, and the continued application of hot-water compresses to the eye. In some cases in which leeching had had but little effect, I have seen dilatation of the pupil follow shortly after the patient had taken a Turkish bath. The measures here mentioned will in the great majority of cases of iritis, if the case is not of more than a week's standing, suffice to break up all or at least most of the posterior synechiæ; and when this has been accomplished the back bone of the disease is broken, and nothing remains to be done but to keep the pupil dilated for some weeks after all circumcorneal injection has disappeared, and to prevent the patient from using his eyes during this time.

But, if after a fair trial of these remedies no marked improvement in the condition of the eye is apparent, or if at any time gummy tumors begin to grow out of the iris, some form of mercury should be administered. Inunction with blue ointment or the oleate of mercury is to be preferred in most cases; but, if there are objections to its use, the bi-chloride, the proto-iodide, calomel, or blue pill may be prescribed. In whatever form the mercury is given, great care should be taken to avoid salivation. As a rule, the use of this remedy should be continued only till the swelling of the iris has subsided and the exudation in the anterior chamber has been absorbed. After that, the iodide of potassium may be given. In former years I used mercury much more frequently in iritis than I do now, having gradually learned from experience that atropine, leeches, and warm fomentations will in most cases break up the synechiæ, if they can be broken up at all by any means outside of surgical procedure. I have even treated without mercury quite a number of cases occurring in persons who had previously had constitutional symptoms of syphilis, and all recovered with the pupil intact and the sight unimpaired. I have also seen a very large gumma of the iris disappear under the iodide of potassium; but it is only fair to add that it did not prevent the development of other gummata in the same eye some months later. I mention this merely to show you that mercury is by no means imperatively called for in iritis occurring in syphilitic patients. Unless other manifestations of syphilis are present at the time, the iritis will require no other treatment than the non-syphilitic variety; but, if constitutional symptoms are present, they should of course be treated in the usual way. I never withhold mercury if I think that the condition of the eye demands it, but I do not give it in any case simply because the patient tells me that he had a chancre. In such a case I at once search for symptoms of syphilis, and if any are found I treat them either with mercury or iodide of potassium; but, if no other manifestations are present, I treat the iritis in the same way as I would in a patient who has never had syphilis.

For the relief of the pain which is so frequently pres-

¹ Read before the Medical Society of New Jersey.

ent during the early stages of an iritis, the repeated application of leeches to the temple is sometimes advisable, even if the pupil is widely dilated; and this plan is to be especially recommended in cases in which morphine does not act pleasantly. Morphine, with or without the sulphate of atropine, should always be given in sufficient doses—either hypodermically or by mouth—to allay pain and produce sleep at night. The hydrate of chloral will answer for the milder cases. During the last few years I have often given the salicylic acid in medium doses with gratifying results in cases of iritis accompanied by much pain in and around the eye, and especially when symptoms of rheumatism were either present or had preceded the eye trouble. Should this remedy fail, quinine may be tried, either alone or in combination with morphia. In my own hands, quinine has been especially useful in cases of iritis associated with gonorrhœa. If the pain is due to an increase in the tension of the eyeball (a symptom not unfrequently seen in severe cases of so-called serous iritis), and none of the remedies mentioned give relief, paracentesis of the anterior chamber should be resorted to. The opening is best made with a lance-shaped knife or a broad needle, at the outer margin of the cornea, great care being taken that the instrument is not pushed far enough in the chamber to wound the iris or the capsule of the lens. If necessary, this little operation may be repeated daily for several days. In nearly all cases of iritis, considerable relief from pain is also obtained from the application to the lids of cloths wrung out of warm water or a warm solution of morphine and atropine. In a few cases the application of iced cloths will be found more soothing to the eye, and the choice between the two may therefore be left to the patient.

Rest in bed in a darkened room, although perhaps not essential to complete and speedy recovery in the milder forms of iritis, should be insisted upon in all cases in which there is much pain, œdema of the lids and ocular conjunctiva, much exudation in the anterior chamber, or a marked increase of tension. In cases of great severity, some relief is also occasionally obtained from gentle diaphoresis; and, as no harm can possibly be done by stimulating the cutaneous secretion, remedies producing this effect may be given in combination with any of those otherwise indicated. Jaborandi, or its alkaloid pilocarpinum, I have occasionally used with apparent benefit in cases in which there was much œdema of the ocular conjunctiva and much exudation in the anterior chamber; and also in cases with marked increase of tension—cases, in fact, in which the inflammation was not confined to the iris, but extended, in all probability, to the ciliary body and the choroid. Of late I have given the pilocarpin exclusively by hypodermic injection. The iodide of potassium, in five to twenty grain doses, is also very efficacious in the same class of cases. An iritis occurring in the course of other diseases—such as syphilis, gonorrhœa, rheumatism, gout, diabetes, small-pox, and so forth—requires no other treatment than that outlined here, care being taken, however, to select for internal use only such remedies as are known not to have an injurious effect on the general disease. That the general disease is to be treated in the usual way is self-evident.

As long as the eye is at all irritable, all close work should be strictly prohibited, even if but one eye is affected; and in order to guard against relapse as much as possible, only a very cautious use of the eye should be permitted for some months afterward.

With regard to the treatment of the results of an iritis, my advice is not to interfere unless the pupil is excluded—that is, the entire pupillary margin is fastened to the lens capsule. In this condition the iris is soon bulged forward by the fluid effusion between it and the lens capsule, and secondary glaucoma follows. As soon as the bulging of the iris is noticed, a large piece of iris should be excised. No other treatment will be of any avail.

An iridectomy may also be made in cases in which numerous and broad posterior synechiæ appear to be the cause of relapses of iritis, although this operation is by no means a sure prevention. Of the several operations devised for the purpose of breaking up posterior synechiæ, without excising iris tissue, I will only say that none but the most skilful operators should undertake them; of their value I am in doubt. Various modes of treatment have been suggested for preventing relapses, and I have tried them all, only to be disappointed in them all. Relapses will occasionally occur in spite of all the remedies recommended.

ULCER AND FISSURE OF THE RECTUM.

By F. W. SMITH, M.D.,

DEMONSTRATOR OF ANATOMY, SYRACUSE (N. Y.) UNIVERSITY MEDICAL COLLEGE.

SOME recent experience in treating diseases of the rectum leads me to think that few diseases of equal importance are so apt to be wholly overlooked by the general practitioner.

I believe that in the female many cases of supposed uterine or bladder trouble, or obstinate constipation, or perhaps chronic diarrhœa, have been unsuccessfully treated, when, if a proper examination of the rectum had been made at the first, the patients could have been saved months, and perhaps years of painful suffering. In the male it is not impossible to mistake rectal disease for beginning cystitis, vesical calculus, enlarged prostate, or urethral stricture. And these mistakes are made not infrequently and by good physicians, not because they are incompetent to make a diagnosis, but rather because of carelessness, or perhaps because their attention is not often attracted by patients afflicted with rectal disease. For some reason a physical exploration of the rectum is rarely thought of unless symptoms point almost positively and exclusively to its disease, while the uterus and urethra are frequently subjected to the most rigid examinations when no symptoms point to local trouble, either functional or organic, with a view of determining if there is not some local derangement which may, through reflex irritation, be the cause, perhaps, of an irritable cough or some other complicated disorder the origin of which is difficult to understand.

The most common disorders met with in the rectum are ulcer and fissure, and although trifling in point of size and pathological relations, they are of great practical importance both on account of the excessive amount of local pain and the constitutional disturbance and irritation to the nervous system which the patient may suffer. As illustrating some of the striking phenomena which are presented by the above-named disorders, I will report three cases such as are liable to fall into the hands of any practitioner, and which are only a fair sample of others which have come under my notice.

CASE I.—November, 1881, there appeared at my office for treatment a Mr. O—, a young man twenty years of age, apparently of strong and vigorous constitution, who said that until his present trouble began he had never been sick for a day.

About two years before he came to me he commenced to have pain of a severe lancinating character, which he located principally about the neck of the bladder, but sometimes darting backward to the sacrum or radiating down the thighs. At first the pain was only occasional, occurring once or twice during the day or night, the paroxysms gradually becoming more frequent until his pain was almost constant.

Defecation became very painful and difficult, notwithstanding that during much of the time the bowels moved frequently and the stools were soft.

Perhaps his most distressing trouble was his almost constant desire to urinate, which act also excited no little pain. For more than a year he had been obliged to pass his water as often as every hour, night as well as

day. About six months before he came to me he underwent an operation for stricture of the urethra, and although his urethra was made proper size, none of his unpleasant symptoms were relieved, but continued to grow worse, and when he came to me he was indeed in a pitiful condition. The countenance was pale, anxious, and careworn, and his expression indicative of constant suffering.

The constitutional disturbance and irritation to the nervous system had been very great, and his condition was such that his father and brother expressed to me fears that his mind was even becoming affected. I examined the rectum and found two large ulcers situated about two inches above the margin of the anus, one anteriorly, oblong in shape, and occupying a space a little smaller than a silver quarter. The other, about half the size of the first, situated posteriorly. Both presented much the same appearance. They were deep, with edges sharply defined.

After stretching the sphincter moderately, I touched the ulcers lightly with the nitrate of silver and prescribed suppositories of iodoform and belladonna to be used at night. The young man returned the next day, saying he had not spent so comfortable a twenty-four hours in more than two years.

I continued the above treatment, moderately stretching the sphincter two or three times a week, and at the end of two months he was relieved of all his unpleasant symptoms and the ulcers healed.

CASE II.—Mrs. R——, twenty-eight years of age, has the appearance of being strong and healthy, and is a woman of good habits. Has had three miscarriages, one at the fourth month and two at the sixth month of utero-gestation.

I first saw her on the morning of September 10, 1882, when she was threatened with another miscarriage at about the sixth month. She was extremely restless and had been having periodical pains for the past ten hours, with now and then a little hemorrhage.

I began to think abortion inevitable and to think of the safest and best means of hastening along the work which had evidently already begun, but being naturally of a conservative disposition, I made haste slowly. I inquired carefully into her previous history, to see if I could find any possible cause for this as well as her former miscarriages; but in my efforts to this end I failed completely, except that I obtained a history of obstinate constipation, with painful defecation and the occasional passage of a little blood, which trouble extended back over a period of more than three years. I began to suspect that my patient had disease of the rectum, the examination of which might reveal the cause of her present trouble. Introducing into the rectum my index finger, I found the sphincter muscle in rigid contraction, also three fissures about equally distant from each other, and extending upward from the margin of the anus for about two inches. I stretched the sphincter moderately and touched the fissures lightly with the nitrate of silver and gave no opiate or sedative of any kind. Returning the next day, I found her very comfortable; her pains had ceased almost immediately after my operation of the day previous, and with no treatment other than attention to the rectum she went on to full term, and on December 20th she gave birth to a strong, healthy male child, weighing ten pounds.

Now, I firmly believe that the fissure and spasm of the anus, from which this woman suffered, were the cause of her three previous miscarriages, and I have not the slightest doubt that she would have aborted this time had not she been relieved of the old irritation and exciting cause.

CASE III.—Miss B——, aged twenty-two years, came under my treatment in September, 1882. She gave a history extending back over a period of more than two years. Her most distressing trouble was painful and prolonged menstruation. She was troubled much with chronic constipation, frequent micturition, and almost

constant pelvic pain. She was also very anæmic and suffered from headache and extreme nervousness.

About a year before she had undergone an operation for stenosis of the cervix uteri, but had obtained no relief.

I instituted a careful examination, and aside from a general hyperæmia and hyperæsthesia, the uterus and its appendages were in a normal condition.

Exploration of the rectum revealed an irregularly shaped ulcer, a little larger than a dime, situated anteriorly about two inches above the anal orifice. With no treatment other than attention to the rectum, and the use of a ferruginous tonic, she was in a few weeks restored to good health.

In the treatment of the above named rectal troubles, I have had much the best success by moderately stretching the sphincter from time to time at intervals of three or four days, in connection with some local application, than by either the operation of forcible dilatation or incision, and the former method has the advantage of being less formidable to the patient.

EARLY ENGLISH MEDICAL AND SURGICAL LEGISLATION.

By MYRON T. BLY, Esq.,

ROCHESTER, N. Y.

A DRAFT of a proposed act, introduced in the early part of the present session of the Legislature, "authorizing" people to employ whomsoever they think fit as medical attendants, smells strongly of "A Bill that Persons being no Common Surgeons may administer medicines notwithstanding the Statute," enacted by Parliament in the thirty-fourth year of the reign of "our most-dread sovereign lord, Henry VIII.," just about three and a half centuries ago. Thus doth history repeat itself, for what is legislation but history compacted and crystallized? The old English statutes mark epochs of progress in the trades and manufactures, in political economy and science, in the learned professions, and what shall we say of their preambles? Between the "whereas" and "wherefore" of those sturdy acts is frequently found the only insight obtainable into contemporary history. The facts are not always reliable to be sure, but they are generally as reliable as any facts which can be obtained from other sources.

It may have been from a lack of inclination, or from a feeling that interest would not warrant it, or from a lack of space in their crowded works, that writers on medical jurisprudence have failed to treat, as it deserves, the subject of medical police. It can scarcely be said that the subject is not included in medical jurisprudence, for it is. It is perhaps a branch; if so, it has arrived at a stage of development which entitles it to a treatment of its own. There is enough material for a work on medical police—a work which might be made valuable to the legal and medical profession and invaluable to the legislator and political scientist. If such a work is ever written, an account of the early English legislation will not only be the natural beginning (unless the writer chooses to delve into the older material of the continental countries) but will also be one of the most instructive chapters. It furnishes the key to all the legislation enacted since, both in England and America, commencing with the "act for the appointing of physicians and surgeons," passed in the year 1511, the third year of King Henry VIII. The first era of legislation looking toward the regulation of the practice of physic and surgery, extends to the thirty-fifth year of Henry VIII., and during this period no less than seven statutes at large were enacted.

Dr. Ordronaux, in his "Jurisprudence of Medicine," speaks of "the earliest statute" as "a draft of an act of Parliament of 9 Henry V., A.D. 1422." Nowhere else have I found any allusion to such an act. None of the authorities on English statutes refer to it, and it is not given in Ruffhead's "Statutes at Large"—an acknowl-

edged authority. Moreover its terms are suspicious, it provided that no one should practise physic unless he had studied in a university and was at least a "bachelor in that science." If such a statute ever existed, how is it that its provision was afterward so completely undone, and why has it taken centuries of legislation to get back again? Paris and Fonblanque have given just a little discussion to police laws in their medical jurisprudence, although finally dismissing it as "but little matter of professional interest." They refer to a petition presented to Henry V., in which was set forth the advancement made on the continent in regulating the practice of medicine, and perhaps what Dr. Ordonaux calls a statute was a portion of this petition.

As to the Act of 1511, there is no doubt of its authenticity. It is constantly referred to by later acts and it seems to have been made the basis of all future legislation. It is an epoch-marking statute. When the Governor and Council of the colony of New York, in 1760, came to frame the first medical police regulation enacted in America, they evidently had this first English statute in mind.

The preamble set forth a truly outrageous state of affairs, alleging that "the science and cunning of physick and surgery is daily within this realm exercised by a great multitude of ignorant persons, of whom the great part have no manner of insight in the same; some also can read no letters on the book, so far forth that common artificers, as smiths, weavers, and women, boldly and accustomedly take upon them great cures and things of great difficulty, in which they partly use sorcery and witchcraft, partly apply such medicines as be very noxious and nothing meet therefore, to the high displeasure of God, great infamy to the faculty, and the grievous hurt, damage, and destruction of many of the king's liege people." Consequently the ban of the law was laid upon "smiths, weavers, and women," and all persons were forbidden to practise physic or surgery in London or seven miles around, unless examined and admitted by the Bishop of London or Dean of St. Paul's, assisted by four chosen physicians or surgeons. In other parts of the realm practitioners were to be examined by the bishop of the diocese, assisted, if he chose to call such, by experienced professionals.

This Act was subject to great abuse in the bishoprics, by reason of the supreme discretionary authority invested in the bishops. It remained unchanged until 1522, when the Act was passed incorporating the physicians of London. The king had already issued letters patent to that body in 1518, for the "due exercising and practising of the Faculty of Physick and the good ministration of medicines." This patent was ratified and enlarged by the statute, which recited a necessity for practitioners to be "profound, sad and discreet, groundly learned, and deeply studied," and therefore the work of examining and admitting them was turned over to the corporation—a proceeding which undoubtedly made candidates "sad" enough. The governing body consisted of eight "elects" vested, among other things, with the power of examining in London persons wishing to practise in any part of the realm.

Very early in its history the "Faculty of Physick" in London began to assume a powerful legal status. In 1540 its authority was made more autocratic by the Act "For Physicians and their privileges," which was procured through a petition which the corporation transmitted to Parliament. The petitioners knew how to excite a lively interest in their prayer, reciting that "divers of them many times having in care some of the lords of your most honorable council." The argument was so irresistible that henceforth physicians were exempted from keeping "watch and ward and to be chosen to the office of constable." The corporation was authorized to appoint four of their number to have "full authority and power, as often as they shall think meet and convenient, to enter into the house or houses of all and every apothecary to search, view, and see such apothecary's wares,

and all such drugs and stuffs as the said four persons shall there find defective, corrupted, and not meet nor convenient to be ministered in any medicine for the health of man's body, the same four, calling to them the warden of the said mystery of apothecaries, shall cause to be burnt or otherwise destroy the same."

Having made this simple disposition of the adulterated drugs question, this Act of 1540 closed by prescribing that, "forasmuch as the science of Physick doth comprehend, include and contain the knowledge of surgery," duly admitted physicians "might practice and exercise the said science of Physick in all and every his members and parts." This latter clause fairly illustrates the position which surgery occupied, as a profession, at this time. It was more of a vulgar than a learned profession. In 1513 a statute at large exempted the "wardens and fellowship of the craft and mystery of surgeons enfranchised in the city of London, not passing in number twelve persons," from jury and constable service and all matter of office. In 1530 it was found necessary for Parliament to enact that surgery was not a "handicraft," thus exempting surgeons from certain restrictions pertaining to handicraft men. The first statute, however, strictly pertaining to surgeons was passed in 1540, the thirty-second year of Henry VIII. If we may believe the preamble of this Act, there were abiding in London "men of great experience as well in speculation as in practice of the science and faculty of surgery," but unfortunately there were two distinct companies exercising the science, one called the barbers of London and the other the surgeons of London. The barbers' company was incorporated by letters patent of Edward IV. The surgeons' company was unincorporated, and therefore the two companies were made one under the title of "Masters or governors of the mystery and commonalty of barbers and surgeons in London." The new corporation was invested with the autocratic powers which had previously been bestowed on the physicians' company, such as the summary "punishment and correction as well of freemen as of foreigners, for such offences as they or any of them shall commit or do against the good order of Barbary or Surgery." Under such a power as this, offenders against good practice were summarily thrown into the common jail, and at a later date Parliament was obliged to restrict the power of these corporations and correct the abuses which had arisen.

One of the clauses of this statute of 1540 allowed the surgeons to take yearly the bodies of four executed malefactors, "for anatomies," which number was increased to six in the time of Charles II., "provided they be afterward buried." Another clause recited that as persons exercising surgery at the same time exercised "barbery, as washing or shaving and other feats," whereby infection resulted, therefore no one "using barbery or shaving" should "occupy any surgery, letting of blood, or any other thing belonging to surgery, drawing of teeth only except."

It was not until the eighteenth year of George II. that a statute was passed giving a modern recognition of surgery. It repealed the Act of 1540 and disconnected the surgeons and barbers. Henceforth surgery was free from the incubus of "barbery." It is thus seen that legislation relating to physicians was far in advance of that concerning surgeons. An illustration of the enlightened view with which the judges regarded the profession of the physician is found in the decision of one of the first cases arising under the statute of 1541: A man was prosecuted for practising contrary to the provisions of that Act, and the Court decided that "practising physick" involved three things: "First, In judging of the disease and its nature, the constitution of the patient, and many other things. Second, in judging of the fittest and properest remedy for the disease. Third, in directing and ordering the application of the remedy to the disease."

We have presented a brief view of the early English medical and surgical legislation. All of its important features are found to have been the work of the first thirty-five years of the reign of Henry VIII. Henry himself was the last person whose mind was calculated to originate and develop such legislation. It must be ascribed to the activity of a far greater mind—that of Cardinal Wolsey—"one, that by suggestion, ty'd all the kingdom."

Progress of Medical Science.

AN EASY METHOD OF POSTERIOR RHINOSCOPY.—The importance of visual inspection of the naso-pharynx and posterior nares in all local diseases cannot be questioned. Ordinarily such examinations are attended with various difficulties. Dr. Walsham (*Lancet*, July 28, 1883), describes a simple method of overcoming these difficulties, admitting, however, that a somewhat similar procedure has for years been practised by some American specialists: A piece of soft red rubber tubing, about one-eighth of an inch in diameter, is introduced into one nostril, and pushed very gently along the floor of the nose till it presents just below the soft palate. It is then gently seized with a forceps, drawn out through the mouth, and loosely tied across the upper lip to the end protruding from the nose, the elastic tube being stretched just sufficiently to loop upward and forward the soft palate, and draw it well away from the posterior wall of the pharynx. The looping of the palate on one side is often sufficient; but a better view is obtained by passing a tube through the other nostril and looping up the soft palate of that side in the same way. The posterior nares and naso-pharynx can now be examined with the ordinary laryngoscopic mirror with the greatest facility. One hand only is required to hold and direct the mirror (the stem answering the purpose of a tongue-depressor), the other hand is consequently free to perform any manipulation or operation that may be required. The tubes serve as a good guide, as they can be followed in the mirror winding round the upper surface of the palate, and so into the respective choanæ. The introduction of the tube causes hardly any discomfort or annoyance to the patient. Care, however, should be taken in passing the tube to let it only just present below the soft palate, as otherwise, if it is pushed further, it may impinge upon the lower pharynx, and is then apt to produce a tickling sensation and desire to vomit. When the examination is finished, it is better to withdraw the tube through the mouth rather than through the nose, and when the nasal end is just about to drop into the pharynx to give it a sharp whisk forward. If it is withdrawn through the nose, the mouth end trails along the tongue, causing a tickling of its posterior part. In place of the red rubber tubes, the American surgeons referred to use flat tapes or narrow bandages for tying up the palate. These have necessitated the use of various instruments for passing them, such as the Eustachian catheter, Bellocq's sound, etc. The advantages of the red rubber tubing are that it is soft, non-irritating, and possesses just sufficient resistance to enable it to be passed through the nose by itself, thus dispensing altogether with the use of an instrument, the passage of which, as for instance in plugging the nares, is, as is well known, a source of much discomfort and annoyance to the patient.

GOOD REMEDIES OUT OF FASHION.—In an address on this subject, recently delivered by Dr. C. J. Hare, the lecturer made some interesting observations on emetics and bleeding (*British Medical Journal*, July 28, 1883). In former times it was not unusual to commence the treatment of many diseases with the administration of a dose to procure vomiting. And although the remedy might then be given sometimes indiscriminately and according

to routine, only those who had seen the effects of emetics, properly and judiciously given, could conceive the beneficial effects they sometimes produced. In the early stage of an attack of croup, it was by no means unusual to give an emetic of tartarized antimony or of ipecacuanha. And it was in accordance with the recorded experience of some of the best authorities and most practical men, and quite consonant with his own experience too, that symptoms which presented the most certain augury of a severe attack were by these means cut short, the hoarse voice resumed its natural character, and the feverish symptoms were in a few hours relieved. He knew quite well that a great fear was entertained by some as to the depressing effects of emetics. But the fear was theoretical, and not practical, and those who had had most experience in the administration of them best knew how groundless the fear was. In diphtheria, too, he had seen the false membranes which were out of the reach of local remedies, and which the patients coughed and coughed in vain, and utterly exhausted themselves to get quit of, readily brought up by the action of vomiting, to the immense relief of the sufferer. "In suffocative bronchitis," the lecturer continued, "the effect of emetics is sometimes magical, and by their administration in such cases not only is immense relief given, but I am certain that lives are saved. You are called to a patient who has been ill a few days, with increasing dyspnoea; she is sitting up in bed (I draw from nature), for to lie down is impossible; she is restless and tossing about; the lips, and indeed the whole face, blue; the eyes watery and staring; the pulse quick and small; the cough constant; the expectoration semi-transparent and tenacious; over every square inch of the chest, front and back, from apex to base, you find abundance of rhonchi; moist, sonorous, and sibilant ones in the upper part of the lungs, and muco-crepitant or mucous râles toward the bases. Ammonia and stimulants, right and good in their way perhaps, in such a case are too slow in their action; the patient is, in fact, more or less slowly, more or less rapidly suffocating. An emetic of twenty-two grains of ipecacuanha in an ounce of water is given; in ten or fifteen minutes the patient vomits and brings up a huge quantity of that tenacious mucus, and the whole aspect of the case is altered; the distressed countenance is relieved; the breathing is at once quieter; and the patient is able, for the first time for the past twenty-four hours, to lie moderately low in bed, and to get some sweet refreshing sleep. The patient is, in fact, rescued from the extremest peril, and in this case, and in many similar ones too, I believe, from otherwise most certain death. Of course, in such cases the emetic is not given for its effect on the stomach, but for its collateral effect in mechanically clearing out the enormous amount of secretion which accumulates in the bronchial tubes, and which the patient is otherwise quite incapable of getting quit of; and thus the half-choking, almost asphyxiated condition is changed for one of comparative comfort, and time is gained for the action of other appropriate remedies. No doubt the secretion may, and often will, accumulate again; and I have not hesitated again in bad cases to repeat the same good remedy; but it is a fact, and a very positive one too, that, quite contrary to what those who have had no experience in the plan suppose, the system rallies instead of being more depressed under the action of the remedy. There is a class of cases in which the right heart is engorged with blood, and in which the only hope of rescuing the patient from death is by bleeding. A man of middle age (I again draw from nature) has considerable chronic bronchitis, with some congestion of the lungs, and, like many other unwise persons, he goes to a southern watering-place instead of remaining in his room and in a uniform temperature. Becoming worse, he determines to return home, and travels on a cold spring day; his dyspnoea is so much worse on the journey, that his friend and the fellow-passengers doubt whether he

will arrive home alive; and when his carriage meets him, it is with the greatest difficulty he is conveyed to his house, and got into his drawing-room. You are at once sent for, the message being that the patient is dying, and when you arrive you find that that is the fact. He is sitting in a chair (to lie down is impossible for him), his face is blue and swollen, his lips purple, the eyes suffused and staring, his heavy gasping breathing you have only too distinctly heard and recognized as you ascended the stairs, and when you see him you find his chest heaving, and each short gasping inspiration followed by a long wheezing and moaning expiration; his lungs are full of moist, sonorous, and mucous and submucous rhonchi, and scarcely a trace of vesicular respiration is to be heard, and he is pulseless. He looks to you beseechingly, and gasps out, in scarcely articulate words, that he is dying. This is but too true. Now, the treatment for such a condition at the present day is 'to pour in stimulants' (though the patient can scarcely swallow). Brandy and water are given, and ammonia, and perhaps ether; then, if the patient live long enough to have them made, mustard poultices are applied to the chest, and to the calves, and to the feet, and the patient is fanned, and the patient dies. Something has been done, but that which true pathology—and, indeed, common sense, unshackled by prejudice, custom, and fashion—would dictate, has been left undone. Appearances have been saved, but not the patient's life. The fact is, that here the danger lay in the right side of the heart being gorged with blood, so that it was impossible for its stretched and distended walls to contract and to propel forward the thick and blackened blood. Relieve that poor oppressed, distended heart, and all may be well. Open one of those veins which are, with every systole of the heart, tending to carry more and more blood to this already distended right ventricle, and all may yet be well with your patient. Sometimes this blood-letting, in extreme cases, is no easy matter; it may be necessary, before you can effectually open the vein, to place the patient's arm in warm water, so as sufficiently to distend the vein; and even when the ligature has been efficiently applied, and the vein well opened, you may have to press and squeeze and rub upward the arm before a drop of the thick and tarry blood will flow. But, when it *does* flow at length freely, what a marvellous change may you see take place!—the breathing becomes quieter, deeper, and less noisy, the haggard face resumes the appearance of tranquillity, the blueness of the skin is replaced by a more natural tint, the pulse becomes more and more distinct, and, in a word, the choked-up heart is set free."

SPLENECTOMY.—Dr. A. Blum has recently written an article upon the subject of excision of the spleen (*Archives Générales de Médecine*). His conclusions, based upon a study of the recorded cases, are that while the operation of splenectomy is practicable and is compatible with complete recovery, it is so often fatal from hemorrhage or shock that it is but rarely indicated. He considers that it is not justifiable in cases of splenic cysts, because they can be cured by other and milder measures; or in cases of hypertrophy, whatever its cause, or in cancer of the organ, on account of the very high mortality. But he points out that in cases of movable spleen, with marked and severe symptoms, the operation is comparatively easy and successful; while in cases of hernia of the spleen following an injury the removal of the herniated portion is so successful that the surgeon is fully warranted in undertaking it.

THE ACTION OF PIPERIDIN.—This substance has been experimented with by Fliess. The results of his researches are given as follows by the *Lancet*, July 28, 1883: If a dose of piperidin be subcutaneously injected into a frog, after a short period of unrest the animal remains remarkably quiet and no longer moves when the foot is pinched, and that this is not due to lesion of the muscles or to paralysis of the motor nerves is shown by

the vigorous movements that are made if the sciatic nerve be stimulated by an induced current. Paralysis of the sensory nerves must therefore be the cause of the lack of response of the animal to sensory stimuli, and the question arises whether it is the nerve or the centre that is paralyzed. The loss of reflex excitability takes place about ten or twelve minutes after the injection of one milligramme of piperidin, and is so complete that even its contact with the eye fails to elicit any response. Recovery of the sensibility occurs at the expiration of twenty-four hours. It has been rendered probable by Kronecker's and Stirling's experiments that a single shock is insufficient to excite a reflex action, and that at least two are required, which must be separated by a short interval only. In his experiments with piperidin, however, Fliess found that the time which elapsed between two shocks in order that a reflex movement should be induced was not altered, but only that the shocks must be much stronger. Hence he arrives at the conclusion that it is not the centre which is acted on by the piperidin, but the conducting agent—the nerve. The paralysis of the sensory nerves only occurred in those parts of the body to which the blood impregnated with piperidin was distributed; in any part of it protected from the action of such blood the sensory fibres retained their function. Further experiments demonstrated that the part of the sensory nerves on which piperidin acts is their peripheric termination. All the experiments proved that neither the muscles nor the motor nerves were in any way affected. Other results observed after the subcutaneous injection of one milligramme of piperidin were that the frequency of respiration fell to one-half the normal amount—that is, from 60 to 36 and 30 per minute. Large doses led to the Stokes' phenomenon, respiration being interrupted for two to four minutes, after which the frog made from three to four deep respirations. In regard to the cardiac beats, their number similarly fell to about two-thirds of the normal, from 54 to 34 per minute. Fliess further made some observations on the action of piperidin on warm-blooded animals, but did not find that its effects, in the rabbit at least, were nearly so well marked, even though fatal doses were administered, and this he attributes in part to the circumstance that piperidin oxidizes with extraordinary rapidity in the body. The frequency of respiration was considerably reduced, the number falling from 200 to 48 per minute, while the cardiac beats rose from 220 to 340 per minute, so that it would appear that the vagal centre was paralyzed. The pupil became widely dilated, and the heart, when death occurred, was arrested in systole.

ANTERIOR LUXATION OF THE PHALANGES.—In a paper presented to the Société de Médecine of Paris, Dr. Thorens takes issue with Boyer, who has denied the possibility of forward dislocation of the phalanges (*L'Union Médicale*, July 22, 1883). He cites several cases recorded by others and one seen by himself. He concludes therefore: 1. That forward luxation of the phalanges is possible. 2. It can occur only after rupture of the anterior and of one lateral ligament. This partial dislocation is accompanied by a certain degree of torsion. 3. Complete anterior dislocation can occur only after the rupture of the anterior and both lateral ligaments.

PREVENTION OF OPHTHALMIA IN THE NEW-BORN.—Dr. Credé returns again to the subject of ophthalmia neonatorum, treated by him in former publications, and urges his colleagues for the third time to adopt his method for the prevention of this disease and the blindness so often resulting therefrom. He proves the value of his treatment in a few words. It is shown by statistics that, whereas formerly a large proportion (fifteen per cent.) of new-born children suffered from this affection, often so serious in its consequences, the number speedily diminished after the introduction of his method, until

finally, for a number of years, no cases at all were seen. Regarding the etiology of the affection he states: 1. That ophthalmia neonatorum is a disease caused by a specific virus identical with that of gonorrhoea. 2. The poison, contained chiefly in the secretion of granular vaginitis, finds access to the conjunctiva during the period of expulsion of the child. 3. Normal vaginal secretion never causes the specific conjunctivitis. 4. Protracted delivery, early rupture of the membranes, and the large size of the child, increase the danger of infection. The author reviews the methods of prophylaxis formerly practised. These may be classed under two heads, the one seeking to obtain the desired result by disinfectant injections into the vagina, the other applying remedies to the conjunctiva of the infant. The first way was barren of results, and the best effects of the second are only obtained, the author says, by his procedure. This consists in wiping the eyes with a clean, wet rag, and then introducing, by means of a glass rod, one drop of a two per cent. solution of nitrate of silver into each eye. He has never seen any unfavorable reaction follow this little operation. This method has been practised in all the lying-in institutions and foundling asylums of Austria since the beginning of the year, and Cr  d   hopes to see it become general everywhere, both in hospital and private practice.—*Centralblatt f  r Gyn  kologie*, July 28, 1883.

THE ACTION OF ALKALIES ON BILE.—Some researches have been made recently by Lewaschew and Klikowitsch on the subject of the influence of alkaline agencies on the composition of the bile. The experiments were made on dogs with permanent fistulae leading to the gall-bladder. No canula was used, however. For twenty-four hours previous to the beginning of the experiment neither food nor drink was administered. It was found that artificial and natural mineral waters had a similar action on the secretion of bile. For some time after the administration of the alkaline waters the quantity of bile flowing from the fistula was diminished. This effect was probably due to the increased flow of bile into the intestines. After this initial period the flow from the gall-bladder became more than the normal. The normal amount had been previously measured. Artificial waters exercised the same influence on the quality of the bile as the natural waters; but different results were obtained with waters of different degrees of concentration. Thus, carbonate of sodium had a more rapid, powerful, and lasting influence on the composition of the bile than sulphate of sodium. Solutions of weak strength were more powerful than those of higher concentration. Hence, those mineral waters whose principal constituent was carbonate of sodium had the greatest influence on the composition of the bile, especially when the carbonate was not present in a high degree of concentration. The higher the temperature of the fluids ingested, the earlier and more marked were the effects.—*Centralblatt f  r Klin. Med.*

THE HYPODERMIC INJECTION OF BLOOD.—In the *Archivio per le Scienze Mediche*, vol. vii., 1883, Dr. Carlo Bareggi presents a *r  sum  * of a prize essay written by him and published in Milan in 1882, upon the subject of the hypodermic injection of blood. His conclusions were derived from physiological experiments upon animals and clinical investigations in disease. Various methods were practised, and blood from different sources was used, but the best results were obtained with defibrinated blood taken from the same species as that of the receiver. In the human subject a donor was selected who was perfectly healthy and free from any hereditary diathesis and, if possible, younger and of the same sex as the receiver. If more than six ounces of blood was desired it was obtained by venesection, but when a smaller amount than three ounces was wanted it was taken by means of a wet cup in the palm of the hand. In the earliest experiments he employed an ordinary

Pravaz syringe, but later, in order to avoid the great number of punctures and the increased danger therefrom, he made use of an instrument similar to that employed by anatomists for injecting the minute blood-vessels and lymphatics.

The author sums up the results obtained, as follows: 1. Hypodermic injections of blood in amounts of one gram are absolutely innocuous. When greater quantities are used, the injections are relatively harmless according to the regions of the body in which they are practised and the method employed. The parts of the body which best tolerate the injections are indicated in the original memoir, where also the best method of operating is described in detail. 2. In man, hypodermic injections of blood are always followed by a slight febrile movement, varying in duration from a few hours to, at the most, two days. 3. The red globules of homogeneous blood, defibrinated or not, injected into the subcutaneous connective tissue, are absorbed, in part at least, unaltered, and pass into the general circulation. Their course is from the lymphatic spaces in the connective tissue into the lymphatic vessels leading from the part, through the glands met with on the way (unless these are in an advanced stage of fibro-adipose degeneration or in some other way profoundly altered), and thence into the receptaculum chyli and thoracic duct. They were found in the principal lymphatic trunks of the part twenty minutes after the injection was practised, and even after three days, numbers of them in a good state of preservation were encountered in the thoracic duct. The greatest number was met with twelve hours after the injection, but even after fifteen days, quantities of red globules, but little changed, were seen passing from the cellular tissue into the circulation. Absorption of the mass of injected blood proceeded rather slowly in individuals in whom the circulation was sluggish, especially in those in whom there was considerable subcutaneous adipose tissue, but more rapidly under normal conditions of the heart's action and in persons in good general condition. The red globules were unchanged after remaining many days in the cellular tissue, except in cases in which there was considerable febrile reaction. 4. Hypodermic injections of blood are capable not only of arresting the progressive deterioration in the quality of the circulating fluid, caused by insufficient nourishment or repeated losses, but also of increasing, in spite of such persistent influences, the corpuscular richness of the blood. 5. This increase in the relative proportion of red globules is equal, or very little inferior, to that obtained by the administration of ferruginous tonics in cases in which these remedies are tolerated. The improvement shows itself very soon after the first injection, and persists long after the treatment has been discontinued. Together with increased richness of blood comes a marked improvement in the general nutrition and neuromuscular force. 6. To obtain such effects, it is necessary to repeat the injections several times at intervals of five to fifteen days, and to inject each time a considerable quantity of blood. In one case Dr. Bareggi made four injections of 100, 100, 120, and 130 grams (3 to 4 ounces) respectively in twenty-nine days. The relative proportion of h  moglobine was more than doubled. In a second case four injections of 200, 300, 150, and 240 grams (4½ to 9½ ounces) respectively were practised in the course of twenty-two days, and the proportion of h  moglobine was nearly doubled. 7. If these results are compared with those obtained by intraperitoneal transfusion, it will be seen that they not only equal but surpass them, and that without any danger to the patient, and by a method at once easy and inexpensive. "In the hypodermic injection of blood, therefore, we have a new and most valuable therapeutic resource. It is especially adapted to the treatment of those cases of slowly progressive an  mia in which the digestive canal is extremely irritable and unfit for the reception, retention, digestion, and transmission to the blood of nutritive materials and medicaments."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 1, 1883.

THE PILGRIMAGE TO MECCA AND THE CHOLERA IN THE EAST.

At the present time, when the danger of cholera is so imminent, a little *brochure* with the above title by Dr. Stékonlis, reprinted in Constantinople from the *Gazette Médicale de l'Orient*, is of peculiar interest. The work is divided into six chapters, treating respectively of the holy city of Islam, the pilgrimage, the health of the pilgrims and of the city of Mecca, cholera epidemics in Mecca, the origin of these epidemics and the prophylactic measures taken against their spread. Mecca possesses a very changeable climate, and is swept with high winds and deluged with frequent storms of rain. The city is dirty and scantily supplied with water—from cisterns and from brackish springs. The water of the holy well in the temple of El Haram is especially foul, muddy in appearance and saltish to the taste, and contains, according to an analysis of Frankland, a large amount of organic matter. The number of pilgrims is variously estimated at from fifty thousand to one hundred thousand annually. The number is, however, gradually falling off, in spite of the command of the Koran that every one of the faithful must visit the holy city at least once during his lifetime. This is due in a measure to the interpretation put upon the injunction by the sect of the Chafie (the Turks), who say that it is binding only upon those who have the means and the health necessary to the journey. The Dutch Government allows none of its Mohammedan subjects to start on the pilgrimage unless he can prove that he possesses means sufficient to defray all the expenses of travel and food. The most wretched and destitute of all the pilgrims, says Dr. Stékonlis, are those coming from British India. The cost of food and even of water in Mecca is very great, and those who come unprovided with money to buy these necessities suffer severely, and fall ready victims to disease. Since 1865 the condition of the pilgrims has been greatly ameliorated by the exertions of the international sanitary commission at Constantinople. It is now forbidden to slaughter animals for food except in certain designated localities outside of the city; inspectors are appointed whose duty it is to see that the pilgrims observe some of the ordinary rules of cleanliness in their lodging-places, and numbers of deep privy vaults have been dug throughout the city. There is a pilgrims' hospital with sixty beds.

From 1813 to 1881 there were sixteen epidemics of cholera in the holy city, all of which, with but one ex-

ception (that of 1846), occurred at the time of the annual pilgrimage. One of the greatest outbreaks of the disease was in 1881, when it lasted from the middle of September to the end of the year. Some 5,000 of the 100,000 pilgrims of that year perished. The disease was carried from Mecca in all directions by those returning to their homes, but was kept out of Egypt and Turkey by the exertions of the health commission. A double quarantine was established for the returning pilgrims. The first, of fifteen days' duration, was at El Medji, on the Egyptian boundary, 375 miles from Suez; and the second, for forty-eight hours, at Jebel-el-Tor, 125 miles from Suez. Another quarantine, of ten days' length, was established at Beyrouth, and all the returning pilgrims were subjected to a second medical inspection before passing the Dardanelles. That the cholera in Mecca is carried thither by the Indian pilgrims there can be no reasonable doubt. The author states that each of the great epidemics in that city was directly dependent upon exacerbations of the cholera in India. In 1882 a quarantine was established on the Island of Camaran, at the mouth of the Red Sea, for all pilgrims coming from India. This island lies 150 miles north from Cape Babel-Mandeb, is eleven miles in length and three and a half miles wide, and is plentifully supplied with pure water. All ships passing through the Straits of Babel-Mandeb were compelled to go to the island of Camaran. There the passengers were landed and examined by the medical officers. If all were healthy, they were allowed to proceed after five days; but ships from a place where cholera existed, or those having cholera aboard, were detained from ten to fifteen days. The southern part of the island was reserved for the healthy, the northern part for the sick. From July 27th to October 20th, 5,518 pilgrims passed through this quarantine to Mecca. In spite of these precautions, however, the disease appeared in the latter city. The explanation of this failure the author finds in the fact that the English protested against the quarantine, and that English ships bearing pilgrims would not submit to the detention at Camaran. The English authorities kept the existence of cholera at Aden secret for thirty-five days, so that Mecca became infected from ships carrying clean bills of health. Dr. Stékonlis states that in 1882 the Egyptian pilgrims, for the first time, returned by water, having always before gone home by caravan through the desert. To this fact possibly is due the present epidemic of cholera in that country. The partial success already achieved by imperfect quarantine of pilgrims going to and returning from Mecca, gives occasion to the hope that greater perfection in the methods now inaugurated, may succeed in removing this source of peril to Europe and the rest of the civilized world. The author seems to think that the only hindrance to a perfect quarantine and the prevention of cholera in Mecca is the refusal of the English to submit to the vexatious, but necessary, delays thereby caused.

THE TIME AND MANNER OF WEANING.

THE Commission permanente de l'Hygiène de l'Enfance of the Paris Academy of Medicine offered a prize in 1880 for the best essay on the subject of weaning. None of the productions offered at that time was deemed worthy

of a prize, so the committee determined to invite further competition on the same subject for 1882. Ten memoirs were sent in in answer to this second appeal, six of which were regarded as worthy of note, and of these, two were especially commended. The report of the committee was made to the Academy at its meeting on June 26, 1883. (This learned Society, it will be remembered, devotes its entire energies to the advancement of science, and eschews politics. Hence its regular meetings are not interrupted from early spring to autumn.) After a short analysis of each of the essays submitted, the report closed with a concise summary of the most practical suggestions contained in the approved memoirs. These conclusions were briefly as follows: Generally speaking, the child should be fed at the breast during at least the first year of life. The term weaning should be understood as indicating the time at which the child ceases to be suckled and begins to be fed with other food than breast-milk. The weaning of an infant fed at the breast should be a progressive process, for too rapid weaning is often attended with fatal consequences. Gradual weaning is best accomplished by supplementing the mother's milk with cow's milk. This should be given in a bottle, as the effort of sucking excites glandular secretion, and, if possible, it should be withheld until the third or fourth month. After the sixth or seventh month a little farina, oatmeal, starch, or bread may be added to the animal milk to make a thin pap. At the end of a year eggs and butter may be used and bouillon may be substituted for milk in preparing the gruel. At the end of eighteen months or two years vegetables and fruits may be allowed, but meat and wine only after this time. The meals should be given at regular hours, twice a day to begin with, and the intervals between the times of nursing should be increased at first during the night. When about to complete the process of weaning, it is important to choose: 1, a time at which the infant is in perfect health; 2, the interval of calm which separates two dental crises, as after the cutting of the third group or the first molar teeth, or after that of the fourth group or the canines; 3, a season of medium temperature, as spring or fall, so as to avoid equally the great heats of summer and severe cold of winter. All the writers commented upon the lamentable ignorance of this subject displayed by the mothers of France (and they might have added, of the world at large), and suggested that mothers and nurses should be instructed in the elementary duties of their station by means either of printed tracts or public lectures. A valuable suggestion, no doubt, but one which it is to be feared will prove very difficult of practical application.

THE QUESTION OF ABUSE.

DR. SQUIBB, in the *Ephemeris*, refers to the "abusive comments" made by some medical journals upon the action of the American Medical Association at its last meeting. It is strange that those gentlemen who have been so active in circulating scandalous charges against New York physicians, should now complain themselves of being "abused." No one can deny that a very large proportion of the profession throughout the country, including men of the highest character, and even the President of the Association himself, think that a change is

needed in the Code. When a few men at Cleveland, therefore, endeavor to strangle all attempts at securing reform and harmony, they lay themselves open to severe criticism. The Cleveland meeting was indeed harmonious, but its effect has been to increase the discord and bad feeling in the profession. For this reason we, in common with many other medical journals, have criticised its action as most unwise and short-sighted.

The charge which most journals have now fallen back upon and content themselves with reiterating, is that the New York Society is in rebellion. It seems impossible for some of our contemporaries to understand, in this connection, one of the simplest principles in law and right, namely: that a chartered and legally constituted body cannot in any sense "rebel" against the regulations of an unchartered body without legal status, with which also the former is only in voluntary relation.

THE MICROCOCCI OF DYSENTERY.

WE admire the courageous diligence of Dr. Prior, of Bonn, who has been studying the micro-organisms in dysenteric passages. Dr. Prior, by special arrangements with a docile patient, caught the dysenteric stools in disinfected bowls, and within five minutes had preparations under the microscope. In that time, he very truly says, few bacteria could get in from outside or could develop from within. He used for his examinations only the purely dysenteric passage, without admixture of fecal matter.

He found in fresh unstained specimens vast numbers of the round cocci. They were in active movement, and were arranged in chains or in pairs, and singly.

They were strikingly like, in size and shape, to the cocci of pneumonia as described by Finkler; of cerebro-spinal meningitis as described by Leyden, and of erysipelas. They were, however, a little smaller and more delicate than those of pneumonia. They possessed active movement.

He also found a few very fine bacilli. The shreds of mucous membrane which were found in the stools were thoroughly washed and examined. Here there were also countless micrococci, but no rods.

In order to compare these appearances with those of health or of other diseases, Prior examined a number of the stools from healthy men and from patients suffering with tuberculous diarrhoea, typhoid fever, and simple intestinal catarrh. He found micrococci and bacilli here also, but the former in extremely small numbers compared with those in dysenteric stools. On the other hand, the bacilli were very much more numerous.

Experiments with staining fluids were made in order to see whether the cocci could be differentiated in this way. They colored beautifully with gentian violet and Bismarck brown, but had no special stain and could not be doubly stained.

Examinations were made of the diseased intestine, fresh specimens, and those preserved in alcohol, and Müller's fluid being used. The micrococci were found not only in the tissue-juice, but in the tissue itself.

The blood was examined a number of times, but nothing abnormal discovered.

The similarity between the micrococci of pneumonia.

cerebro-spinal meningitis, erysipelas, and dysentery is, to Dr. Prior, a very suggestive fact. To us it appears that the attempt to find a pathological unity or consanguinity between these diseases is rather strained.

Prior does not pretend to say that the organisms he describes are the cause of dysentery. He intends, however, to make some gelatin-cultivations of them, and then inoculate the younger generations. He expects to be able to show that dysentery will be produced.

NOT ENOUGH MEDICAL COLLEGES.

OUR brilliant, but infrequent (being quarterly), contemporary, the *Fort Wayne Journal of the Medical Sciences*, reasserts its view that there are not too many medical colleges in the country. It does not now, however, go quite so far as to say that we need more. Following its able editorial upon the present beatific state of medical education, especially in small western cities, is this notice:

"The medical college of Fort Wayne was closed out, a few days ago, by the constable selling all of the furniture and illustrations in the entire concern to satisfy a judgment against the institution."

We are pained to observe that our contemporary seems rather pleased than otherwise at the collapse of this institution, although it leaves the country one precious college the less.

The history of medical institutions at Fort Wayne is only a repetition of what has occurred over and over again in other places. Medical men, not content with achieving success by the quiet method of ordinary practice, desire to be professors; and thereupon they organize a school. The institution cannot take in all the ambitious doctors in the town; therefore, discontent and jealousy ensue. A rival college is organized, good feeling is disturbed, bitterness and quarrelling arise, and the harmony of the profession broken.

Now, is all this necessary for the sake of crudely educating a few medical students? We think not, although it grieves us, in saying so, to controvert our excellent and too infrequent contemporary of Fort Wayne.

THE PRESBYTERIAN HOSPITAL, NEW YORK.—Arrangements are now being made for increasing the capacity of this hospital and thereby extending its usefulness. The governors are contemplating the erection of a new pavilion, and also the appropriation of some of the spare room in the executive building for extra beds. A new passenger elevator has been erected in the main building, and a new ambulance, which is claimed to be the best made and most complete one in the city, has been recently presented to the institution. Since the establishment of the ambulance service in this hospital the number of acute surgical cases has increased to such an extent that the wards are constantly crowded to their utmost capacity. The attending staff proposes to utilize this material for free clinical instruction to students and practitioners during the coming fall and winter.

TYPHOID FEVER IN COUNTRY RESORTS.—It is reported that typhoid fever has shown itself in several country resorts.

News of the Week.

THE VACATION OF PHYSICIANS AND THE HEALTH OF NEW YORK.—The health of New York is very good, considering the season. This may be probably due to the fact that a large number of invalids have been sent to the country to recruit. At least the larger majority of fashionable physicians do not consider it worth while to remain in town for purely business purposes. Those only who are sick need the physician, and the physician needs only the sick. Both being temporarily separated are now enjoying a rest. With the coming fall, both will doubtless return to work with renewed vigor. The latter is often needed more by the doctor than the patient in these days of active competition in practice.

THE NEW PRESIDENT OF THE HEALTH BOARD OF THIS CITY is giving great satisfaction by close attention to business and energetic endeavors to initiate practical reforms in his department. He is constantly in his office and gives personal attention to details.

THE TRI-STATE MEDICAL SOCIETY will meet in English's Hall, at Indianapolis, on September 18, 19, and 20, 1883, commencing at 9 A.M. Excursion rates have been secured on the following railroads: C., C., C. & I.; Cin., Indianapolis, St. Louis & Chicago; Cin., Wabash & Mich., Indianapolis & St. Louis; I., B. & W.; Wabash, St. Louis & Pacific; Indianapolis & Vincennes; J. M. & I.; Pitts., Cin. & St. Louis; Vandalia, Evansville & Terre Haute; Ft. Wayne, Cin. & Louisville. The New Denison, Grand, Bates, and Brunswick have reduced their rates for the occasion, and everything promises a very large attendance. Many papers of great interest will be presented. For further particulars address Thos. B. Harvey, M.D., Indianapolis, Chairman of Committee of Arrangements. Dr. Wm. Porter, of St. Louis, is President, and Dr. G. W. Burton, of Mitchell, Ind., Secretary.

GETTING THE BEST OF A QUACK.—A quack with many aliases but generally known as the Indian Medicine Man, was recently prosecuted by the Illinois State Board for violating the Medical Practice Act of that State. The quack was accustomed to give public exhibitions of his quackery at different towns in the State. On one such occasion at Decatur complaint was made against him, a license which he had fraudulently obtained was revoked, and he was placed under bonds of \$500 for each violation of the law in the shape of an exhibition. He gave but two of the latter and then decamped.

THE UNITED STATES MEDICAL COLLEGE—DECISION BY THE SUPREME COURT.—We are in receipt of the decision handed down by Judge John R. Brady of the Supreme Court, in relation to the case of the so-called United States Medical College, represented by Dr. Robert A. Gunn and others. The charge against this institution, it will be remembered, was that the defendants were, under the act of June, 1882, illegally acting as a corporation without authority, and were exercising privileges and franchises not granted to them by law. It had previously been determined that the act of 1848, for the formation of charitable, literary, scientific, and benevolent societies, under which the defendants set up their cor-

poration, did not provide for or authorize the incorporation of medical colleges to give instruction, issue diplomas, etc.; and that the law of 1882 did not legalize the incorporation. In this view Judge Brady also concurred. In rendering this decision it was held that the law of 1882 related to scientific and literary colleges and universities, and not to medical colleges, since such language was not employed in the wording of the Legislative act, it being presumed that that body was advised of medical colleges, etc., in the premises. Judge Brady's concluding remarks are worthy of note, viz.: "The courts of this State cannot be too scrupulous in examining the asserted right of any college to graduate matriculates with the degree of doctor of medicine, and to grant them diplomas conferring such degree. The high and responsible duties of a doctor of medicine, relating as they do to suffering humanity, and life itself, and requiring for their proper discharge a high order of culture, experience, and capacity, there should not be the slightest doubt about the due and legal incorporation of every college or society assuming the power to confer upon him the necessary degree, and thus enable him to practise as a physician and surgeon."

PREPARING FOR CHOLERA IN PARIS.—At a meeting of the Municipal Council of Paris, on July 27th, a grant of four hundred and eighty thousand francs was voted to provide for the construction of a temporary hospital for cholera patients in the event of an outbreak of that disease. The buildings are to be erected on one of the bastions of the line of fortifications, and will provide accommodations for two hundred patients. Should the cholera not put in an appearance the hospital may be used for the reception of small-pox patients, or of those suffering from other contagious diseases.

PROFESSOR WILLIAM OSLER, of McGill Medical College, Montreal, has been elected a Fellow of the Royal College of Physicians of London, England. Dr. Osler has held the chair of physiology in the above college for many years, and has done much good work in original investigation. He is at present general secretary of the Canada Medical Association. He is a young man yet, and is to be congratulated on the honor of attaining to the F.R.C.P. solely as the result of his scientific labors.

CHANGES IN MEDICAL COLLEGE PROFESSORSHIPS.—The following are some of the new appointments to professorial chairs, which we find mentioned in our exchanges: Professor Parvin has been tendered the Chair of Obstetrics in the Jefferson Medical College, recently made vacant by the resignation of Professor Wallace. The vacancy in the Faculty of the University of Louisville, made by Dr. Parvin's resignation, has been filled by the appointment of Dr. John A. Ochterlony. Dr. Roswell Park, of Chicago, editor of the *Medical Review*, and connected with the Chicago Medical College, has recently been called to the Chair of Surgery in the Medical Department of the University of Buffalo, N. Y.

THE CODE IN ST. LOUIS, AND HOW A RECENT OFFICIAL STATEMENT IS CONTRADICTED.—At the meeting of the American Medical Association, in Cleveland, Dr. S. Pollak, member of the St. Louis Medical Society, offered a resolution to the effect that a committee be appointed for the purpose of revising the code of ethics, and that

this committee "be authorized to prepare a code of ethics which in their view will meet the wishes of the profession, and submit the same to the meeting of 1884." At a subsequent meeting of the St. Louis Medical Society a resolution was adopted repudiating the action of Dr. Pollak, and expressing the fealty of the Society "to the existing code of ethics as a time-honored and most suitable fundamental law of the profession," and deprecating "any action calculated to reflect upon its loyalty to those principles which have heretofore secured immunity to the machinations of schismatics within or enemies without." Thereupon Dr. Pollak published, in the *St. Louis Medical and Surgical Journal*, a certified copy of an extract from the minutes of the meeting of the St. Louis Medical Society of June 2, 1883. At this meeting it was resolved unanimously that the delegates of the Society to the meeting of the American Medical Association "be requested to move for the appointment of a committee of one member from each State, for the purpose of taking into consideration the propriety and advisability of a revision of the code." The delegates were further instructed to invite the delegates from the State of Missouri to join with them in presenting this resolution to the American Medical Association. Dr. Pollak appears to have had the best of the argument thus far.

MEETING OF THE VIRGINIA STATE MEDICAL SOCIETY.—The fourteenth annual meeting of the Medical Society of Virginia will be held at the Rockbridge Alum Springs, Va., commencing on Tuesday, September 4, 1883. It will be an important meeting, as the Constitution and By-Laws of the Society, and resolutions for the government of the organization generally, will be considered. The Springs Company offers free hotel accommodations to the delegates, and the railroads are selling tickets at greatly reduced rates to those desiring to attend the meeting. Several papers of presumable scientific value are promised by gentlemen in and out of the State.

GAILLARD'S MEDICAL MONTHLY.—Our esteemed contemporary, *Gaillard's Medical Journal*, has returned to its old form as a monthly, after appearing weekly for eighteen months. The reasons for this change are stated to be the wishes of its subscribers, as well as the fact that there is now no monthly medical journal published in this city, while of weeklies there are several.

THE PROGRESS OF THE YELLOW FEVER.—During the past week there has been but little increase of the scourge at the Pensacola Navy Yard, and hopes are entertained that the disease has been arrested by the sanitary precautions which have been inaugurated by those in charge, only four new cases (the wife and daughter of Dr. Owen, Paymaster Brown, and Lieutenant Whipple) having developed since our last report, and two deaths, that of Assistant Surgeon Owen, U. S. N. and his wife. The villages of Woolsey and Warrenton, located upon the reservation, and populated by the lower classes, have had several cases of yellow fever and one death. At the request of Lieutenant Commander Welch, of the Navy Yard, who feared an epidemic in these villages, Surgeon General Hamilton authorized the employment of five sanitary policemen to make a house-to-house inspection, for the purpose of placing them in a good sanitary condition, and discovering any cases of yellow

fever that might be secreted by the inhabitants. He also authorized the employment of an expert physician to take care of such sick poor who might be afflicted with the disease, in case an epidemic occurred, and were too sick to be transferred to the quarantine hospital, the intentions being to remove all sick as soon as possible from among the well. On August 22d, quite an excitement was created in the city of Pensacola, by the officially reported occurrence of two cases of yellow fever on Palafox Wharf, and many of the citizens took flight. Acting Assistant Surgeon White telegraphed the fact to the Surgeon General Marine Hospital Service, who directed that the cases be immediately removed to the hospital on Santa Rosa Island, and to disinfect the premises, destroy the bedding and clothing of the men. On the following day one of the men who were removed to the quarantine hospital died; an autopsy was held by Surgeon Murray and Assistant Surgeon Leonard, who pronounced the disease from which he died to have been "pernicious swamp fever," and that the other one, who was still living, was suffering from the same disease and not from yellow fever. This diagnosis would seem to be borne out by the facts subsequently learned regarding these cases; it appears upon investigation that the two cases of supposed yellow fever were deserting sailors from the bark Dagmar, from Limerick, who arrived at Reed's sailors' boarding-house, on Palafox Wharf, on August 17th, after three weeks spent in the country, hiding in the swamps and awaiting the departure of their vessel. The Dagmar sailed from a healthy port, brought a clean bill of health, made a long voyage, and was not detained at quarantine, as she was in a good sanitary condition, and there was no occasion for detention. The vessel cleared for Dordrecht, on August 17th, the day these deserting sailors put in an appearance at Pensacola. The house-to-house inspection at Pensacola has been completed, and the city is now considered to be perfectly healthy and free from yellow fever. Hospital tents, disinfectants, experienced medical men, are on the ground, in case yellow fever should appear. Reports from Vera Cruz, Mexico, continue to come in, showing that the disease is still very fatal among the shipping. Sanitary Inspector Mainegra telegraphed on August 24th, that the steamers City of Merida and Discoverer cleared from that port on August 23d, bound for New York. Sanitary Inspector Burgess, in his abstract of bills of health ending August 18th, reports the steamers Alabama for Key West, Saratoga for New York, Cristobal Colon for New York, Ellie Knight for Key West, City of Alexandria for New York, schooner Damietta for Key West, and bark Maria for New York, having sailed during that week. He also reports forty fatal cases in Havana during that period.

THE JOHNS HOPKINS HOSPITAL.—It is said that the medical department of the Johns Hopkins University, of Baltimore, will probably be opened about October 1st. Two of the university professors, Dr. Remsen and Dr. Martin, have been assigned, respectively, to the chairs of chemistry and physiology.

THE ANNUAL REPORT OF THE NATIONAL BOARD OF HEALTH, for 1881, has been delayed unavoidably, but made its appearance this week. †

SURGEON BURGESS telegraphs that the mate of the Spanish bark Suiciro, which sailed for New York on the 23d inst., was put ashore at Havana, suffering from yellow fever. Forty deaths from yellow fever occurred at Havana last week.

A DESPATCH from Colon (Aspinwall) states that there is no yellow fever at that place this year, and that the port is in a good sanitary condition.

ASSISTANT SURGEON GUITERAS, U. S. N., has reported for duty at the Pensacola Navy Yard, and has just submitted his report of inspection of the port of Vera Cruz, Mexico, to the Surgeon-General. We hope to give some items of interest from it next week.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE NAVY, for 1881, has just come from the hands of the Government printer. A notice of its contents will appear soon.

SPECIAL SURGICAL APPLIANCES TO THOSE DISABLED IN THE MILITARY AND NAVAL SERVICE.—Congress having appropriated a small sum for furnishing special surgical appliances to those disabled in the military or naval service, Surgeon-General C. H. Crane, U. S. A., is desirous of obtaining authentic information regarding all existing cases of severe and unusual injuries. As no money commutation is authorized, only such cases need be presented as offer a fair prospect of being relieved by surgical or mechanical appliances. Artificial limbs and apparatus for disabled limbs being otherwise provided for, by law, the injuries here in view are almost exclusively those affecting the head, face, or trunk. As trusses are furnished under special legislation, hernia, when not complicated with other injuries, is not to be understood as covered by this appropriation for *special* appliances. As the appropriation is small, it is proper that it be expended only on the most meritorious cases. It is therefore not intended to furnish appliances which are ordinarily within the means of the individual, nor those that are of a character so perishable that it would be difficult to keep up the supply. Regard is to be had chiefly to the severity of the injury, and the ability of the sufferer, unassisted, to procure relief.

THE STATE MEDICAL SOCIETY OF WISCONSIN will hold an adjourned session at the Court House in the city of Milwaukee, commencing on Tuesday, September 4, 1883, at 8 P.M.

DEATH FROM CHLOROFORM IN OLEAN, N. Y.—A colored man, aged thirty-two years, died suddenly in Olean, N. Y., while under chloroform, which was being administered to him for amputation of the toes. From the evidence at the coroner's jury it appears that every care was used to guard against a fatal result. But a very small quantity of the drug was used. Death was evidently caused by heart failure.

ADVERTISING SURGICAL OPERATIONS.—We are receiving from day to day slips from newspapers sent us by subscribers detailing the wonderful exploits of surgeons in different parts of the country. They form very amusing reading, and show that the ignorance of the lay press regarding the importance and rarity of such operations is only equalled by the shameless audacity of the advertisers.

Reviews and Notices.

INQUIRIES INTO THE HUMAN FACULTY AND ITS DEVELOPMENT. By FRANCIS GALTON, F.R.S., Author of "Hereditary Genius." 8vo, pp. 380. New York: Macmillan & Co. 1883.

SUCH as have read the author's work on "Hereditary Genius" will be prepared to appreciate in some degree the scope of the present one. The title itself is suggestive of a wide range of study, and considering the painstaking endeavors of the author, it is a very appropriate one. The inquiries are much beyond the range of similar ones on the nature and conditions of man's mental relations, and show a tendency to dive far below the ordinary level of scientific investigation or metaphysical study. It opens to the student of man a field many parts of which have heretofore been but little explored. Curious and instructive facts are brought out, which may serve as valuable data for future theories of mind-working, and for the proper appreciation of the influences of the development of the higher faculties upon the advancement of the race.

The work is made up of a number of papers scattered in various publications, and although by condensation and interpolation the subject-matter has been worked into a consistent whole, traces of its fragmentary origin still remain. This gives it more of a suggestive than encyclopædic character, and excuses the omission of much of that statistical detail of facts which would otherwise appear to be necessary. Although the reader is oftentimes made to feel that in many instances only the corner of the curtain is lifted between what is known and what is possible to be known, he is constantly surprised to find how broad the border-line is, and how conscientiously and thoughtfully it has been explored by the writer.

In all his studies the author has taken a wide grasp. He deals with the manifestations of human intellect and character on a large scale and in their relations to the universe. Consequently he is given to grouping his facts from many and different sources, and basing his conclusions upon ample statistical demonstrations. Take, for instance, the subject of composite portraiture, so intensely interesting to every student of human constitution and human character. Here he proves that there are general characters belonging to the same type of face which can be consistently combined in a single portrait. Members of families show this correspondence in a striking degree, and while particular features may differ there is generally present what is called a family resemblance—a something which places the individual in his family group. The principle of composite portraiture eliminates slight difference by bringing out the stronger features, and hence a consistent picture of the family type. The manner in which this is done is interesting and suggestive, especially to a medical man given to the study of the faces of disease, the evidences of constitutional power, and the appreciation of racial peculiarities in their broadest sense. Photographs of each individual are taken exactly the same size and exactly full-face. These photographs are superimposed in book-form so that the different features exactly correspond with each other. The book of portraits is then fixed and focussed, and by turning the leaves with regularity and rapidity a combination of these portraits is made upon one plate, each component portrait helping to make a single well-defined composite picture. The author's remarkable success in this line is evinced not only in the composite portraiture of family groups, but of other types in individuals with no consanguineous ties. For instance, there are composite portraits of six and nine cases of tubercular disease, respectively, composite portraits of one hundred and fifty cases, respectively, of the so-called healthy type, and numerous other instances. According to our author there appears to be no actual limit to the combinations which can be made under the

circumstances. This certainly opens up a wide field for the study of disease, not only in its bearings upon the face, but upon other parts of the body. What might not be gained by accurate photographic representations of deformities and their composite portraiture in settling upon some absolute standard for comparison. Indeed, the wide application of this method would necessarily suggest itself to the medical man intent upon studying disease and its various manifestations on a comprehensive scale.

Carrying out the same idea the author attempts to apply it to the study of man in all those leading mental and bodily faculties which make him a factor in the great scheme of human evolution. Hence we find our author discussing the propriety of anthropometric inquiries in order to determine their eugenic relations to the human family; in fact, advocating all such measures as may tend by methods more or less mathematical to measure the amount of energy, force, and vitality in large numbers of men, and thereby establish standard types. As preliminary to these ends he studies the various faculties of energy, sensitivity, character, and mental imagery. Some very curious and suggestive facts are brought out in these studies which it would hardly be necessary to detail here. It is sufficient to say, however, that they are capable of being summarized into general principles of great value and extended application. The number of exceedingly interesting data which the author presents regarding mental imagery in reference to number, forms, color, perceptions, and word associations deserve a passing reference. By large correspondence and extended inquiry he proves that a certain class of individuals possess the power of recalling persons and scenes before their mind's eye which is truly remarkable. Not a few can bring up an image in imagination in all its perfections of size, shape, and solidity. This is a faculty possessed by inventors, artists, and others, and, like many similar mental peculiarities, is strongly hereditary. Again, many persons have the same visionary associations as regards numbers. The latter to some appear before the mind's eye in tabulated arrangement, to others in wavy lines, each wave occupied by a particular number. With colors the same curious arrangement oftentimes obtains, and to the visualizing sense in some persons they are associated with particular letters, particular sounds, or even particular ideas. Beyond a certain point it can be easily imagined that positive hallucinations must result.

The development of mental faculties, in all their relations, individual and cosmic, has been, as quite well shown by our author, the combined results of natural selection and natural evolution. Man is, after all, nothing but an insignificant factor in the universe, and simply and irresistibly does his part in carrying out the scheme of advancing civilization, of perfect organization, and higher development. As a part of the whole he is forced to be a consistent worker. It is quite surprising, in view of our author's facts and deductions, to see how little man, as an atom, an individual, can control what, for the want of a better name, we may call his destiny. Admitting modifying influences upon character or organization they are only operative to a limited extent. This is certainly an encouragement to do our best under all circumstances. Still it can hardly be expected that a man with the character of a fox can be made into one with the guileless disposition of a lamb. The difficulty of constructing a silk purse from a pig's ear is well enough appreciated by every one who has tried the experiment. Nature is one thing and nurture is another thing. Our author contributes some very interesting corroborative proof in regard to these points in his histories of twins. Notwithstanding some twins have been widely separated, have had different surroundings, and been subjected to different educational training, they have been known not only to have the same bodily ailments at the same time, but to experience simultaneously novel sensations, mental and bodily, and even to think upon the same subject at the same

time, using almost the same words to express their ideas. These, with other facts, help our author to the conclusion that illness and death are necessary incidents in a regular sequence of constitutional changes beginning at birth, and upon which external circumstances have little or no effect, or, as our author still more strongly puts it: "In cases where the maladies of twins are continually alike the clocks of their two lives move regularly on at the same rate, governed by their internal mechanism. When the hands approach the hour there are sudden clicks, followed by a whirring of wheels; the moment that they touch it the strokes fall. Necessitarians may derive new arguments from the life histories of twins."

These deductions very naturally prepare the way for a discussion of theocratic influences upon man's destiny, as may be manifested in the objective efficacy of prayer. Some very curiously suggestive statistics are presented on this point, proving that man's will is not God's will, and that faith without works is dead. In other words, no proofs are presented to show the purely objective efficacy of prayer in preventing sickness, in hastening recovery, in staying a pestilence, in changing the seasons, stopping a drought, or checking a flood. Whatever may be said of his view of the question the facts upon which his deductions lay are very interesting.

Enough has possibly been said of this truly interesting and instructive book to give the reader an idea of its purpose and scope. If not so systematically arranged as regards its subjects as might have been expected, there is this excuse to be offered, that each component part is complete in itself, each subject has been carefully worked over before as a separate article, and, as previously remarked, the author has done his best to make a proper connection between them. The reader is left free to make his own deductions, and arrange his arguments as may best suit his purpose in view of the facts presented. In a general way we may assume that the work will be valued mostly for the interesting facts it contains rather than the positive strength of many of the arguments used. In fact, not a few of the latter are loosely presented and illogical. Aside from the idea that the development of man is a part of the grand scheme of evolution, all else appears as mere conjecture. We confess that we cannot understand the subject further, and no arguments of the author have increased our light. But his facts will remain, the labor in their arrangement will be appreciated by scientist and philosopher, and his views will be suggestive if some of his arguments are wanting in conclusiveness.

POISONING FROM BLUE STOCKINGS.—Dr. C. C. Stockard, of Columbus, Miss., sends us the following: "In your issue of November 25, 1882, is the report of a case of 'Poisoning from red Stockings.' I have just seen a case of poison from stockings of a different color. Willie M—, aged eight years, had been going barefoot during the summer up to the latter part of July, when he accompanied his father on a trip to Tennessee. He was absent two or three weeks and during this time wore navy blue stockings. A few days before returning home there appeared on his legs, from just above the knee down, a number of red elevations which developed pustules in three or four days and presented the appearance of ecthyma. The pustules were much thicker on the left than on the right leg, and there were several also on the back and chest. These were further advanced than those of the legs, and I regarded them as of similar nature to a crop of small furuncles which he had been having before leaving home, and on account of which he had taken the trip. He returned improved in general health and suffered only from the legs; so that I think there can be no doubt about the stockings being the cause of the ecthymatous eruption. In the case reported in *THE RECORD* the poison was found to be a salt of tin used in setting the dye, but in my case I am unable to say what the poisonous principle was."

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 27, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

PUERPERAL THROMBUS—ENDARTERITIS—DRY GANGRENE.

DR. R. E. VAN GIESON presented portions of the right femoral, the right popliteal, and the left femoral artery, with a portion of the left femoral vein, with the following history, by the attending physician, Dr. J. A. Jenkins, of Brooklyn: Mrs. H. H—, thirty-two years of age, of delicate frame and health, free from all specific taint, was first treated in 1876 for subinvolution of the uterus and cardiac disturbance from mitral insufficiency. In 1878 she passed through a normal confinement and made a good recovery, without increase of cardiac difficulty.

In 1880 she had an attack of rheumatism with severe præcordial pains, dyspnoea, and pulmonary congestion, from which she slowly recovered after several weeks' illness. Since that time she has been more or less under medical care, and at various intervals has taken preparations of digitalis for the relief of difficulty caused by the heart lesions. During the last pregnancy preceding her death she enjoyed unusually good health and was quite free from circulatory disturbance, and altogether free from the renal complications not unfrequently observed during the latter stages of gestation.

On April 25, 1883, she had an easy normal delivery, the child weighing about seven pounds, and fairly well nourished. Some three hours after the birth she had several attacks of syncope, apparently hysterical, relieved by stimulants and anodynes. The following morning she was comfortable and free from all pain; there was no rise of temperature during the attack. With the exception of debility and want of appetite, she did well until May 8th, when her temperature rose to 101°, reaching 102° on May 10th, accompanied with slight tenderness over the uterus. This disappeared after the administration of quinine and opiates, and turpentine stupes.

May 15th.—Had a severe attack of palpitation and dyspnoea, continuing with intermissions some three or four hours. The following five days she had again improved, and on May 20th declared herself strong enough to go down to her meals. During the night she was taken with a severe burning pain in the right foot and leg.

May 21st.—The pain continues. Temperature in the mouth, normal. The right foot and toes are extremely cold to the touch and ecchymosed. The right leg and thigh is colder than upon the opposite side, and the seat of burning, stinging pain. Fair pulsation in the femoral, but faint in the popliteal space.

May 22d.—Discoloration of the skin has extended to the ankle, and complete blackening of the skin over the lesser toes.

May 23d.—Was examined in consultation with Dr. R. E. Van Gieson. Right leg: lesser toes sloughing; skin on dorsal and plantar aspect of the foot of a dark mahogany color; external aspect of the leg discolored in spots; the skin tense, but not œdematous; the whole leg is exquisitely tender to the touch. The left leg is tender, but nowhere discolored, and extremely painful to the touch. Both extremities are cold. The right femoral has moderate pulsation, but is not compressible; the left femoral pulsates very feebly; it is difficult to determine whether, indeed, it pulsates at all. There is no pulsation in either limb at the internal malleolus. The patient lingered in great pain, but little relieved by large doses of opiates, until May 29th, when death was welcomed as a release from her intense suffering.

Permission was granted to examine the limbs only.

Necropsy. May 29th, 5 p.m.—Both crural canals and right popliteal space examined. On the right side the

tissues in Scarpa's triangle are more adherent than in health, the sheath of the femoral vessels is thickened, the cellular tissue is abundantly infiltrated with serum. The vein and artery adhere firmly, requiring careful dissection to separate them. The right femoral vein contains a clot completely filling the vessel and partially organized. The right femoral artery from a slight distance above the origin of the profunda to some four inches below this point is filled with a firm laminated thrombus, adherent and organized, the adventitia and media are very much thickened, the intima is of a dull color, corrugated and reddened. The left femoral space showed the same condition of things in a less degree. There was less evidence of inflammatory action in the immediate vicinity of the blood-vessels, the vein and artery were adherent. The left femoral contained a clot, not adherent, apparently not organized, and not completely filling the vessel. The artery is smaller, less thickened than the right, and contains a small central fibrinous thread, not obstructing entirely the lumen of the vessel. The coats of the right popliteal are thickened, the intima lustreless, the lumen not obstructed.

The question which arises in connection with this case is whether or not the gangrene has any relation to the puerperal state. Endarteritis to this extent, completely occluding the lumen of a large vessel, is uncommon. He had seen but one similar case, which occurred in a male, and was not associated with any disease of the heart whatever. In that case gangrene began in the hand and extended up to the elbow-joint without forming a line of demarcation. The patient was seen by Dr. Markoe, who pronounced it a case of idiopathic endarteritis. Dr. Van Gieson had him under observation for some time after that, but finally he escaped from his observation and he never learned what the ultimate result was. Phlegmasia dolens is a common enough condition after parturition, but it is not limited to the puerperal woman. The question is whether the condition of things that gives rise to puerperal phlebitis might not also give rise to inflammation of the artery by extension of the inflammatory action; or whether some condition of the ovarian veins might not produce the same result. It was the opinion of the attending physician in this case that the cause of the gangrene was an embolus arising from detachment of a vegetation from the valves of the heart. Emboli, however, rarely obstruct vessels of this size, and although that may have been a factor in the etiology, Dr. Van Gieson was not inclined to give it the weight which the attending physician had attached to it. Thus far he had been unable to find a similar case. He was not inclined to attach the condition of the vessels to the puerperal state in the relation of cause and effect.

DR. GERSTER said the specimens seemed to show evidence that the assumption of the physician with whom Dr. Van Gieson saw the patient was probably the correct one. He thought that in the presence of a cardiac lesion, such a possibility of embolic obstruction was very probable. The size of the vessel thus occluded is small in the majority of cases, but there were cases on record in which the embolus was quite large, sufficiently so to completely obstruct vessels of considerable size. The view that inflammation beginning in the veins and extending into the artery did not seem to be borne out by the ordinary experience of surgeons. It is well known that not only simple adhesive inflammation, but a much more violent process, even of a septic character, involving the vein, is not usually transmitted to the arteries, and if transmission does finally occur, the arteries are involved at a very late period in the disease, and in most cases only after extensive destruction of tissues has taken place.

Another argument which seemed to support the embolic theory was the fact that the gangrene came on so rapidly. True arteritis obliterans is a chronic process, the walls of the vessel presenting an uneven appearance,

with hard nodules scattered throughout the coats, so that the lumen of the artery does not retain its cylindrical shape, but presents different diameters at different portions of the vessel. In this instance, however, there was, so far as the cylindrical shape of the channel in the artery was concerned, a normal appearance, and there was arteritis, such as is usually seen after embolism has occurred. The characteristic changes of true arteritis obliterans Dr. Gerster thought were absent.

DR. BEVERLY LIVINGSTON referred to a case in which the patient died sixty-two days after delivery, at the Nursery and Child's Hospital. The woman had swelling of both legs, and he was able to trace the femoral artery and veins to the spot where the clot was arrested. On the left side the obstruction began at Poupart's ligament and extended downward in both vessels until it reached the posterior part of the thigh, and also extended into the profunda. On the right side the thrombus extended downward about five inches. His impression was that there was no cardiac disease. The case was one of complicated labor, the patient being delivered of twins, and the second child was delivered with instruments about six hours after the birth of the first child.

DR. FERGUSON referred to two cases in which thrombi were found in the aorta. One case had already been reported to the Society. The second was that of a female patient who had been in the hospital for about five months, and presented all the ordinary symptoms of chronic diffuse nephritis. The heart was enormously enlarged, but there was no other evidence of valvular lesion. The arteries were atheromatous, especially the aorta, and attached to the posterior wall of the abdominal aorta was a clot. The entire clot was about five inches long, tapering at each extremity, and was attached to the wall of the vessel to the extent of from half an inch to an inch. Its central portion was completely broken down, but the external portion of the thrombus was quite completely organized. In neither of these two cases was there any evidence of valvular lesion of the heart.

DR. VAN GIESON said he wished to bring forward two points in connection with his specimen. First, was the obstruction consequent upon the puerperal state? Second was it a mere accident of the puerperal state? With the remarks made by Dr. Gerster he agreed in the main, and was ready to concede that a very extensive inflammatory action might remain constantly in the vicinity of an artery without affecting the vessel itself. That is well recognized. But the question arises whether an embolus is necessary to the production of this condition of things within an artery; whether or not the death of the intima which always precedes the formation of a thrombus, is necessarily caused by an embolus. He said no, there are other causes. There are conditions of the blood, the nature of which we do not know, which do produce death of the intima, followed by the formation of a thrombus. The question therefore is, whether this death of the intima is caused by the inflammatory lesion *per se*, through lack of nutrition in the artery itself, or whether it is caused by irritation produced by an embolus. In this case a large artery was completely obstructed. If the embolus produced the obstruction it must have been arrested somewhere in the vicinity where the inflammation was produced, or there must have been transmitted from the place where the inflammation was produced an inflammatory action which extended upward to the point where the vessel was occluded, because at that point the coats of the vessel were permanently thickened. He did not believe that it was necessary to assume that because a person has valvular disease of the heart, an embolus is necessary to cause this condition of affairs; for he had seen the same condition produced in the brachial artery where repeated and careful examinations of the heart failed to elicit the slightest evidence of cardiac disease. He did not deny that embolism was a common cause of the condition developed in his case, but that it was the

universal cause he did not believe. He thought there was in the blood of anæmic, chlorotic women, who had long suffered from disease of the heart, to which was superadded the exhaustion of child-bearing, a condition of things which might produce obstruction of the artery without necessarily supposing that an embolus is carried into the circulation. So far as the pathology of phlegmasia dolens is concerned, it is very obscure. That such a condition of things as would produce phlegmasia dolens might also produce arteritis of this kind he thought was scarcely probable. That was merely conjectural on his part. The view that inflammation had extended from the vein to the artery was also conjectural, and the theory merely occurred to him for a moment while he was reading the history of the case.

DR. BEVERLY LIVINGSTON presented

TWO HEARTS FROM CASES OF CYANOSIS IN NEW-BORN CHILDREN.

CASE I.—A male child, two days old, that I had under my care while interne in Bellevue Hospital. The labor had been normal; child breathed and nursed well at first, but on the morning of the third day, he was suddenly attacked with arrest of respiration, and irregular action of the heart; the face became very blue, and in a few seconds the whole body was intensely cyanosed; now the child as rapidly lost the blue color and turned red, and as the breathing and pulse became normal the skin assumed its natural color. The attack lasted about one and one-half minute. During the day the child had six similar ones, about one hour between them, the last attacks were more severe than the first, and lasted about two minutes, artificial respiration had to be employed to bring the child out of them, but after the sixth nothing would cause the heart and respiration to start again; between the attacks the child seemed perfectly well. These attacks of cyanosis came on without cause or warning, there was no muscular spasm accompanying them. Physical examination gave the lungs as normal; the heart a murmur at the base and another at the apex, both systolic. The diagnosis was an open foramen ovale and some disease of the tricuspid valve.

Autopsy.—The right heart was found very much distended with blood, the left heart nearly empty. The foramen ovale was not open, but the ductus arteriosus was. The mitral and tricuspid valves were fringed with the usual reddish, semi-transparent nodules, over which there is so much dispute. The lungs showed numerous small regions of collapse. The other organs were normal.

CASE II.—A male child, born normally, of a healthy mother, at the Nursery and Child's Hospital on May 25, 1883. For the first four days the child was perfectly well; then suddenly he was found to be cyanosed, with shallow, irregular breathing, and irregular pulse; under treatment the child revived, but soon relapsed, this occurred several times the first day (May 29th), during the ensuing three days the child had similar attacks, but did not recover at any time sufficiently to nurse, and remained cyanosed; it gradually lost strength, and died on June 1, 1883. Auscultation during life had given a systolic murmur, heard loudest at the apex. No diagnosis was made. It was supposed the mother had overlain the child during her sleep.

Autopsy.—The body was of a dusky red color all over. On removing the sternum the heart seemed enlarged, but this enlargement was found to be due to the distention of the right side by dark clotted blood. The left side was empty. The foramen of Botall was widely open, as was also the ductus arteriosus. The mitral and tricuspid valves presented the usual fringe of reddish, semi-transparent nodules. The lungs were entirely collapsed except the right apex, which was partially expanded.

These two cases of cyanosis do not show any malformation, or change in the heart due to disease, that would cause the cyanosis. It is true that in the second case

the foramen ovale was found very widely open, and the blood-clot passed from the right to the left auricle; still it seems to me the cause of the cyanosis lay in the disturbance of the circulation due to the collapsed lungs, and not to the open foramen ovale or ductus arteriosus. In the first case the attacks of cyanosis seemed to depend much more on the irregularity of the respiration than on the action of the heart. Hænoch¹ particularly refers to diseases of the lungs as a cause of cyanosis, and open foramen ovale and ductus arteriosus, and similar remarks are made by Cadet de Gassicourt,² Meigs and Pepper, and others.

As to the meaning of the little nodules on the edges of the mitral and tricuspid valves, I must say I do not believe they are of an inflammatory origin, for out of 136 autopsies on children between still-births or a few hours up to three and a half years, I have never failed to find them when I looked for them, and generally the younger the child so much the more pronounced are they. It may be objected that most of these children died of disease, having had more or less fever, but that could not account for the cases dying from the effects of operative midwifery, etc., unless one insists that in these cases they had been foetal endocarditis, which I cannot admit, neither can I accept the idea of Parrot,³ first announced by Luschka,⁴ and lately brought forward again by Hænoch,⁵ viz., that these nodules are the result of rupture of the intravalvular blood-vessels, causing a hæmatoma, which in the course of time underwent absorption and gave, as a result, these semi-transparent nodules; but I rather incline to the idea of Richard Pott⁶ that they are remains of the foetal valve, and are not due to any pathological process. They are composed of a collection of the normal elements of the valve, and do not appear microscopically like the deposits of an endocarditis.

The explanation of the systolic murmurs is difficult, for the only point of resemblance is the open ductus arteriosus, while the open foramen ovale in the second case might explain matters. It would not do so in the first, and I am loth to believe the fringes of nodules could have interfered with the closing of the valves. Some authors (Cadet de Gassicourt) think the passage of blood through the ductus arteriosus can cause a bruit, so this may have been the cause of what was heard. That there were bruits I am sure, but I am unable to give a good explanation of what caused them.

DR. LIVINGSTON also presented a specimen illustrating

CONGENITAL PULMONARY STENOSIS.

The patient was a female child, aged one year eight months, admitted in April, 1882, to the Nursery and Child's Hospital for heart disease. On admission she was a fairly nourished, pale child, with good appetite, regular bowels, normal urine, and parents gave a history of congenital heart disease. She was not cyanotic, she was short of breath, preferred to remain quiet in a chair, her fingers were not club-shaped at the ends, nor was her abdomen enlarged.

Physical examination gave the lungs healthy. Heart, a murmur, systolic in character, very loud, heard with greatest intensity about the junction of the fourth left rib with the sternum, could be heard nearly with the same distinctness at apex, was heard to left of apex-beat, which was in the sixth interspace, and could be heard in the back between the scapulae. There was a distinct fremitus when one placed the hand over the præcordial region. The abdominal organs were normal. The diagnoses were: 1, trouble with the aortic, most likely regurgitation; 2, mitral, a double murmur. I am responsible for the last.

On June 20, 1882, the child developed ulcero-mem-

³ Arch. de Physiol., No. 4, a. 5, 1874. ⁴ Virchow Archiv., bd. xi., heft 2.
⁵ Loc. cit. ⁶ Jahrbuch Kinderheilk., b. xiii., s. 29.

branous stomatitis, and six days later died of septæmia, the stomatitis having been of a mild nature.

Autopsy.—The lungs were normal. Heart was hypertrophied, and the left side dilated. The three semilunar valves of the pulmonary artery are grown together so as to leave a round hole two millimetres in diameter to allow the blood to pass to the lungs, and on one side there is a small vegetation which must also have been an obstacle to the current of blood. The foramen of Botal was enlarged and open, the inter-auricular septum was very much thinned and there were some small holes through it, so it had a cribriform appearance. The mitral and tricuspid valves were normal. The ductus arteriosus was not examined. The liver presented the abnormality of having no gall-bladder, there being only one duct, and that led directly into the duodenum; the transverse fissure divided the liver in two nearly equal halves. The other organs were normal.

This is one of those cases in which there is sufficient obstruction to the blood leaving the right heart to cause the foramen ovale to remain open, and still there was not sufficient cyanosis to have called attention to it. The blood must have mixed freely enough through the foramen ovale, and still cyanosis was not produced, for the lungs were in good condition and the blood was well oxidized. This case supports the theory I put forward in the cases of cyanosis, that the cyanosis was due to obstruction to the circulation in the lungs, not to the mixing of the dark with the red blood. The autopsy explains the bruit that was heard.

Dr. Livingston further presented a specimen illustrating

CONGENITAL COMMUNICATION BETWEEN THE RIGHT SIDE OF THE HEART AND THE BEGINNING OF THE AORTA.

This heart was removed from the body of a male child, three months and twenty-seven days old, he was born in the Nursery and Child's Hospital, March 25, 1882, of healthy mother, was a strong, healthy child, and never gave any symptoms of heart disease. Being put on artificial food he got entero-colitis in July, and died on the 28th of that month.

Autopsy.—Lungs healthy, thymus gland large. Heart enlarged. On opening the aorta, just at its commencement and on the right side, a communication was found leading into the right heart; above and below the tricuspid valve it was closed by a part of this valve, and most likely no blood passed through it. The valves of the aorta are only two in number, but were sufficient to close the opening. The mitral and tricuspid valves were normal, on the mitral are plenty of those semi-transparent nodules referred to in the other cases.

Dr. Livingston also presented specimens derived from a case of

HEREDITARY SYPHILIS.

Male child, born in the Nursery and Child's Hospital May 8, 1883, appeared healthy at birth, but poorly nourished. On May 28th he developed an eruption consisting of blebs on an inflamed base, they appeared first on the soles of the feet, palms of the hands, and between the fingers, in a few days similar blebs appeared upon the limbs, body, face, etc.; after the contents of the blebs became purulent they dried up and left thick yellow scabs. There were successive crops of this eruption. Soon the anus became fissured and presented mucous patches, fissures appeared at the angles of the mouth and an ulcer on the median line of the hard palate. Sprue developed, snuffles appeared, and the child died of asthenia, June 12th, just five weeks old. The child was bottle-fed. The mother gave no specific history, but spoke of having had sore eyes. The glands were not enlarged. Child was treated by inunctions of mercurial ointment.

Autopsy, June 13th, 3.30 P.M.—Child poorly nourished, length nineteen and one-half inches. Hair well developed all over head. The remains of the pemphigoid eruption on the feet, legs, thigh, back, hands, arms,

and on the face around the mouth. Lungs commencing catarrhal pneumonia in the posterior and lower portion, numerous ecchymotic spots in the anterior portions. Heart: foramen ovale open, mitral and tricuspid valves show the small semi-transparent nodules. Spleen firm, Malpighian bodies prominent, $2\frac{3}{4}$ inches long, $1\frac{1}{2}$ wide, $\frac{1}{4}$ thick. Liver congested and was resistant, but could not see any change. Bones: the femur presents at the apex and lower line of ossification a marked yellow line, which is described by O. Haab¹ as due to syphilis, and he claims it to be a change in the basement substance of the cartilage due to infiltration with small cells, so causing a degenerative change but no true pus; the epiphysis can in this way be separated completely from the diaphysis. In the specimen I present, under the microscope no infiltration of round cells can be seen but rather a molecular change.

(To be continued.)

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE VALUE OF BLOOD-LETTING IN PNEUMONIA—CREMATION IN FRANCE—SANITARY REFORMS IN FEAR OF CHOLERA—THE EFFORT TO PREVENT THE ABUSE OF TOBACCO—HONOR TO PASTEUR AND BRÉAL—DEATH OF PROFESSOR PARROT.

PARIS, August 10, 1883.

PROFESSOR HARDY lately delivered a clinical lecture at the "Charité" Hospital, on the advantages of bleeding in some cases, a remedy, he said, that was too much neglected now-a-days, and stigmatized as absurd and dangerous the practice of blindly following fashion and routine in medicine. For his part he has found it an invaluable remedy in certain forms of pneumonia, the very cases in which in his student days he was taught to employ it, and after a practice of nearly forty years, he saw no reason why he should give it up. At the same time he would not have it understood that he would employ venesection in every case, any more than he would any other remedy unless clearly indicated as in the following example: A man thirty-seven years of age, and a gardener by profession, was admitted to his ward with lobular pneumonia of right lung, and pleuro-pneumonia of the left side, of four days' standing. The constitution of the patient was apparently good, though he had had two attacks of pneumonia previously, the first in 1869 and the second in 1879. On the day of his admission the patient was bled to four hundred grammes in the morning, and the same repeated in the evening, and no medicine was prescribed beyond a little gum julep and tisane. On the third day a slight improvement had taken place in all the symptoms, but the patient was nevertheless bled to two hundred and fifty grammes, which afforded further relief, and the improvement continued steadily. On the fifth day the respiration and the other physical signs were normal, the patient began to eat and drink as usual, and he left the hospital a few days after, completely cured and without any other medication.

There exists in France a society for the propagation of cremation; but this manner of disposing of the dead meets with so little favor amongst our neighbors that it is questionable whether it will be adopted in this country. The society, however, is using its best endeavors to point out the advantages that would accrue to the public health by the adoption of cremation, instead of interments, particularly during epidemics of infectious diseases. A petition to that effect, and signed by eminent men, has been submitted to Parliament by the Société de Crémation, of which M. Kœchlin-Schwartz is president; and one member of the society, M. Cadet,

¹ Virchow's Archiv, b. 65, s. 366, f.

who is also a deputy, has proposed that, were cholera to break out, cremation should be made compulsory. This is evidently impossible; but there would be no valid reason why cremation ovens should not be built in two or three cemeteries as an experiment, and a means of testing public feeling in the matter. The substitution of incineration, or any other mode of disposing of the dead, for burying will be a work of time, as deeply rooted prejudices are not so easily overcome.

If cholera has not yet made its way in this country, the fear of its doing so has aroused the French from their wonted apathy, and sanitary reforms are being introduced on all sides, while others are in contemplation, so that Paris, at least, will at no distant period compare with any other city in the civilized world. Among the reforms proposed are the enlargement of the hospitals now in existence and the erection of others for infectious diseases, as well as an asylum for the aged, and another for incurable children, which are to be built outside the walls of the city, and for which the Municipal Council has granted a sum of 3,000,000 francs.

The French society against the use of tobacco has petitioned the Chambers to increase the duty upon tobacco, with the view of limiting its use as much as possible. But however advantageous this measure may be to the revenues of the State, I hardly think it would be of much service in improving the moral and physical condition of the population, which the society has in view, as it is a well-known fact that the more a thing is forbidden and the greater the restrictions put on it the more it will be sought and indulged in. Experience has shown this in regard to spirits, which, notwithstanding the heavy duty levied on it, is more than ever consumed in various forms. The practice of smoking among youths, which is growing to an alarming extent, seems to be the great care of the society, and although heavily taxing tobacco may limit its use to a certain extent yet it is evident that this measure is insufficient to prevent its abuse, and in order to produce some effect in that direction the sale of tobacco to children must be strictly forbidden; parents themselves should set a better example, and every possible means should be taken to instruct the people concerning the deleterious influence on the system of tobacco and alcohol, the two greatest curses of civilized life.

On the occasion of the jubilee of the University of Zurich the diploma of honorary doctor was conferred on MM. Pasteur and Bréal, the well-known French savants.

Dr. Alfred Naquet, the distinguished chemist, but better known for his political position in the French Parliament as Deputy, has been elevated to the Upper House as Senator.

Professor Parrot died on the 5th instant, at his residence in Paris, at the comparatively early age of fifty-three, and after an illness of only two months. Dr. Parrot began his studies in medicine in 1840, and passed successively through the grades of Interne, Doctor of Medicine, and Agrégé, which latter he attained in 1860. In 1876 he was promoted to Professor of the History of Medicine; and in 1877 was appointed Physician to the Asylum of the "Enfants Assistés."

ONE EXCUSE FOR QUICK TREATMENT.—One of the Vienna surgeons was one day called in hottest haste to see the little son of a well-known Austrian count. On reaching his patient he found a trifling scratch on the child's hand. Sitting down and writing a prescription he gave it to one of the servants with instructions not to lose an instant, but to bring the medicine as soon as possible. "And is the danger so imminent, then?" asked the countess. "No, not that," replied the Professor; "I only feared lest the wound should be entirely healed before the servant returned."

THE BEST METHOD OF KEEPING A HYPODERMIC SYRINGE in working order is to try it every day.

New Instruments.

A NEW MOUTH GAG.

By W. THORNTON PARKER, M.D.

ACTING ASSISTANT SURGEON, UNITED STATES ARMY.

IN a recent case of strychnine poisoning, it was with the greatest difficulty that I was able to introduce a stomach tube, owing to the patient's violently grinding his teeth. The tube was finally bitten in two soon after reaching the stomach, and thereby rendered perfectly useless. There being but this one tube in the hospital, the operation of the stomach pump was brought to a speedy termination. It occurred to me at that time that some sort of mouth-gag for making the operation of emptying the stomach more certain should accompany each stomach pump. I have, therefore, devised a simple mouth-gag, made for

me by Messrs. Geo. Tiemann & Co., New York, which I believe will be found very desirable for use with the stomach pump. It is made of hard polished rubber and separates the teeth sufficiently to permit the safe passage of the largest stomach tubes. A strap confines it securely and the patient cannot expel it from the mouth. It is to be hoped that it will prove to be of service.

MIDDLETON, J. V. S., Major and Surgeon. Relieved from duty at Fort Hays, Kan., and assigned to duty at Fort Leavenworth, Kan. S. O. 169, par. 2, Department of the Missouri, August 18, 1883.

WILLIAMS, JOHN W., Major and Surgeon. Granted leave of absence for one month, on Surgeon's certificate of disability. S. O. 109, par. 1, Department of the Columbia, August 8, 1883.

BARTHOLF, JOHN H., Captain and Assistant-Surgeon. Assigned to temporary duty at Vancouver Barracks, W. T. S. O. 109, par. 2, Department of the Columbia, August 8, 1883.

KIMBALL, JAMES P., Captain and Assistant-Surgeon. Relieved from duty in Department of the Platte, and to proceed to New York City and report in person to the President of the Army Medical Examining Board for duty as a member of that board, *vice* Surgeon Clements, relieved. S. O. 193, par. 2, A. G. O., August 22, 1883.

FINLEY, J. A., Captain and Assistant Surgeon. Relieved from duty at Fort Concho, Tex., and assigned to duty at Fort Stockton, Tex., as Post Surgeon. S. O. 101, par. 1, Department of Texas, August 16, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending August 25, 1883.

AUSTIN, A. A., Assistant Surgeon. Ordered to Naval Hospital, New York.

CRAIG, T. C., Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to the U. S. S. Minnesota.

CRAWFORD, M. H., Passed Assistant Surgeon. Detached from the U. S. S. Pinta and placed on sick leave.

WILLSON, W. G. G., Passed Assistant Surgeon. Detached from the Minnesota and ordered to the Pinta.

WHITE, CHARLES H., Surgeon. Ordered to the Museum of Hygiene, Washington, D. C.

BRYAN, J. H., Passed Assistant Surgeon. Detached from the Museum of Hygiene and ordered to the Miantonomoh.

GUIERAS, D. M., Passed Assistant Surgeon. Ordered to the Navy Yard, Pensacola, Fla.

Medical Items.

CENTRAL SEPARATION IN PLACENTA PRÆVIA.—Dr. J. M. Ward, of Cornelia, Mo., has, during thirty years' practice, met with three cases of central implantation of the placenta, which were attended successfully, as well as an equal number of partial cases. In his experience, he mentions that examination will show the placenta separated for a short distance around the internal os, but that hemorrhage occurs only with the pains; hence he advises that the finger be introduced and the placenta peeled off as far as the finger can reach from around the os, after which he tampons until the pains become expulsive. In this view the doctor states that central separation and the tampon gives a good chance for the child, and does not materially impair the chances for the mother. In the second stage the tampon is removed and the following advised: either (a) to peel off the remaining placenta on one side, to rupture the membranes, turn the child, and deliver by the feet; or (b) after having peeled off the placenta on one side, to rupture the membranes and bring the fore edge of the placenta through the os, and hold it against the side of the vagina until the head engages. By this procedure about four inches of the central portion of the placenta is reached, leaving two inches of the circumference to maintain foetal life and circulation. This, he advises, should be done early, by which means full dilatation is permitted, with no more laceration of the curling arteries.

HOW TO KEEP THE HYPODERMIC SYRINGE IN ORDER.—One of our subscribers, G. E. A., writes: "Your correspondent of last week desired to know how to keep his hypodermic syringe in working order. The following has been my experience. Of course the best way with any and all instruments is to use them. Next to that, *inspect them regularly* once a month—not only look at them, but look at them with an oiled rag and piece of chamois skin, more carefully in summer than in winter. In considering hypodermic syringes, aspirators, etc., the instrument should be regarded in two parts—the barrels and pistons, which require the *wet treatment*, and the needles and wire, trocar and canula, which require the *dry treatment*. If the piston-leather is old and worn out it should be renewed; but if only dried and loose from non-use, draw a little warm water into the syringe, then, placing the finger over its end, slowly press the piston downward through the water, which will be seen to pass between the piston and sides of the syringe. The water will now be both above and below the piston, and will cause its leather to swell quickly and make a tight joint. In order to keep it so discharge the water from both ends of the syringe, and treat in the same manner with

glycerine, which, being hygroscopic, keeps the piston-leather in good condition. Moreover, pure glycerine will not become rancid, as will oil, etc., nor will it interfere with any chemicals used hypodermically. In the larger syringes a harder fat like mutton tallow will often cause the piston to work better than oil or glycerine. If the piston should have become so tight that it is impossible to make the glycerine pass above it, invert the syringe in glycerine or put a few drops around the piston-rod, and then slowly press it downward. The glycerine will follow into the upper chamber and will ply back and forth with the piston and keep it in order. The test for a tight piston is to put the finger over the end of the syringe, and quickly pull up the piston-rod, when, if tight, a vacuum will be formed and the piston return to fill it. The 'dry treatment' for the needle consists in blowing out all liquid from them by several quick strokes of the piston, while the needle points upward, so that no fluid from the syringe enters it; if used but seldom, let this be done in the hot, dry air just above the lamp or gas. After removing the needle from the syringe replace the wire. Should the morphia gradually form a crust upon the inside of the needles, hot water may be drawn through them, or a quicker and more thorough way is to secure from Tiemann & Co., or other instrument maker, a yard of hypodermic wire (uncut), fasten one end, thread the needle upon the other, and then with a few long strokes it is quickly cleared. When one allows his patient to suffer ten or fifteen minutes' extreme pain while fixing his hypodermic syringe, or, as I have seen, a patient almost lose his life because his physician's stomach-pump would not work, it seems duty and but little trouble to *inspect* for a few moments, the first day of each month, those instruments which ought to be kept in order."

Dr. W. N. Williams, of Indianapolis, Ind., says: "Place a piece of soft rubber between the needle end of the syringe and end of the case, thick enough with a corresponding piece at opposite end of case to make it fit the case snugly, then fill the syringe with water both *in front* and *behind* the packing, place in case and the syringe will be kept water-tight and ready for use even if it is not filled oftener than once in ten days. I should be glad to hear of a better way if there is one."

ANOTHER THREE-BARRELLED PENIS.—Dr. E. B. Ward, of Greensboro, Ala., writes: "Seeing the article headed 'A Three-Barrelled Penis' in THE RECORD of August 11, 1883, brought to mind a similar case of mine. A young gentleman called at my office for treatment, and on examination I found that the same anomaly occurred in this case as the one mentioned by you, *i.e.*, the meatus presented three distinct openings. Not only was this anomaly of the penis confined to him, but his two other brothers presented the same rare specimens of malformation."

THE SO-CALLED ABORTION OF TYPHOID FEVER AND THE INVESTIGATION OF PRETENTIOUS CLAIMS.—Dr. E. Ruthven Young, of this city, writes: "Having long been an eager and instructed reader of THE RECORD, in perusing its number of May 26th, I came across, to me, a rather unsatisfactory article, headed, 'A Confident Correspondent.' In it you will readily see, by reference to your file, that a Dr. Davy, of Ohio, takes a decided exception to an article published in a February number of the *Medical Age*. The writer of this latter seems to have made in it the assertion that 'Typhoid fever is a disease which is uncontrolled and uncontrollable, and *any one* who says he can abate an attack or cut short the disease after it has passed the forming stage is either a *knave* or a *fool*.' Dr. Davy, in his short comment on this, says, after a reference to poor Galileo as being badly used for his great discovery, that 'within the next five years typhoid fever will be controlled almost as easily as remittent or marsh fever.' God grant he may be right in this, for if so, surely we will have a weapon second only to Jenner's vaccination. Further, he says 'a patient can

be gotten into a convalescent condition in from four to six days after the following symptoms are fully developed : temperature, 105° ; pulse, 100 to 120; nervous symptoms with delirium well marked; tongue dry and cracked; articulation indistinct; bowels tympanitic, tender, and gurgling; diarrhoea of ochre-colored stools, etc. Ninety per cent. of such cases can be gotten up and about in 12 to 18 days by *proper medication*. Now, Mr. Editor, such an assertion attracted me at once. Having read widely concerning typhoid, and never having heard of anything so nearly approaching a specific as this seemed to promise, I determined to avail myself of the professional courtesy of Dr. Davy and obtain this valuable knowledge. Yet even then it struck me as peculiar that the doctor should stop so suddenly and give the world of physicians no clue as to what this 'proper medication' was. What a pity such knowledge existed and the profession not have it and their suffering patients its benefit! In answer to my anxious letter of inquiry, I received a letter from which I give sufficient extracts for my brothers in ignorance to learn as much as I did: 'Dear Doctor, etc.—We have never given the chemical working formula to any one. We have spent much time, hard study, and money in obtaining our knowledge, and as some chemist has to prepare the compound, we thought it but right to retain the formula. Any one desiring the therapeutical knowledge and sufficient of its chemistry, so that they may handle cases of typhoid fever just as intelligently and successfully as we have done or can do, such information will be cheerfully given. The medicine will be manufactured by — & Co., and sold at two dollars a pint.' Now, Mr. Editor, where are our much-talked-of ethics? To which class does this compound belong, patent or proprietary? Perhaps it may be valuable, but as a 'secret nostrum' it will never be respected or used by our noble brotherhood of *true* physicians."

MEDICAL MEN IN PARIS.—The Paris correspondent of *The Lancet* states that a list of the members of the medical profession, practising in its various branches in Paris and its environs, has been drawn up under the orders of the prefect of police, and consists of 1,915 doctors of medicine, 12 doctors of surgery, 83 *officiers de santé*, 43 foreign medical men, 1,500 *sages-femmes*, 845 *pharmaciens*, and 95 veterinary surgeons. The list is to be posted up at each police station for the benefit of the public, and at the same time to act as a check upon those who have no right to practise. Among the foreign medical men authorized to practise in France, ten obtained their diplomas or degrees at the Faculty of Jena, the others in various universities of England and Germany. Among the doctors of medicine there are two ladies, one French and the other Russian. This list would give an average of one medical man to about 1,100 inhabitants, the population of Paris being estimated at 2,239,928. The following interesting information has also been obtained by the prefecture *à propos* the above list. The senior medical man, according to age, is M. Ségalas, who was born in 1792, and took his degree in 1817. Next in seniority comes Dr. Ricord, the celebrated syphilographer, who was born in 1800, and took his degree in 1826. The oldest *sage-femme* is established at Bourg-la-Reine, in the Department of the Seine. She obtained her diploma in 1815, since which she has continued to practise without any interruption. She declared at the prefecture of police that during the sixty-eight years she has been in practice, she had, on an average, 100 *accouchements* a year, so that she has during that period brought 6,800 children into the world.

TREATMENT OF GENU VALGUM BY THE FRENCH SURGEONS.—Dr. A. J. Steele writes concerning the above subject (*St. Louis Courier of Medicine*) as follows: "At Lyons I was warmly received by MM. Mollière, Robin, and Delore. All had done original work in the matter of genu valgum or knock-knee, and I was anxious to learn more of their investigations and treatment.

Delore is more especially interested in and is teaching obstetrics and gynecology, but several years since he investigated the subject of in-knee, and proposed as a method of treatment fracture through the epiphyseal junction both of the femur and tibia. This is done by manual force over the edge of the table. The limb being thus straightened, is put up in starch or plaster-of-Paris dressing, and the patient allowed to be up and about; union occurs in an improved position. He reports cases thus treated and cured. But I do not find that his professional brethren are very generally adopting this method, many preferring in the young subject to employ mechanical appliances worn for a long period, and thus gradually straightening the limb. In the youth and young adult, M. Robin breaks the femur above the epiphyseal junction with an osteoclast of his own devising. M. Mollière, surgeon-in-chief of the *Hôtel-Dieu*, has in many cases adopted this method very satisfactorily. He showed me in his wards several cases that had undergone the operation, some still in the starch dressing, and others with it removed, all doing well and with no untoward results. At his kindly suggestion M. Robin applied his instrument to the limb of a cadaver in order to illustrate its action to me. It was an adult subject, and the femur was broken very readily with his osteoclast just above the condyles. On cutting down upon the part the periosteum was not, at least on the anterior part of the femur, broken, though the bone was fractured entirely through. In badly united fractures, and in ankylosis of the knee and hip-joints, the same instrument has been used by them to break up the part and allow of improved reposition."

SMALL DOSES.—Dr. Thorowgood says regarding the use of small doses:—"I have come to the conviction that the doses of many medicines, as set forth in books, are often needlessly large, when we seek, not an eliminant or evacuant effect, but a gradual alternative or specific action from the remedy. There is probably no medicine regarding the definite action of which physicians agree better than iron; but is it necessary for the cure of facial neuralgia to give an insoluble powder like the hydrated oxide of iron in a dose ranging from thirty grains up to three or four drachms? The subnitrate of bismuth, another insoluble powder, has been given for the relief of gastric pain in such large doses that, after death, large, hard, black masses of concrete subnitrate and sulphide of bismuth have been found blocking the intestinal canal. The gentleman who made the post-mortem said the masses he removed looked like lumps of metal." As to calomel, he has seen marked beneficial results from the administration of doses of one-third of a grain, and he has found patients do much better with doses of two minims of tincture of aconite than with doses of five to fifteen minims as prescribed in the *British Pharmacopœia*. He also advises small doses of liquor arsenicalis for the relief of spasmodic asthma, and he has seen excellent results from the persevering use of small doses (one-fiftieth) of a grain of strychnia in promoting the restoration of exhausted nerve-function, "while larger doses do but add to irritation and eventually increase the exhaustion." Tincture of nux vomica taken in doses of one to two minims, fasting every morning, he has found useful in the cure of chronic constipation.

A CURIOUS INSTANCE OF FEAR OF BEING "BURIED ALIVE" has just been brought to notice by the proving of the will of Major Andrew Gammell. This gentleman deposed that a sum of one hundred guineas, free of legacy duty, should be paid to Mr. Barnard Holt, F.R.C.S., or failing him, some equally eminent surgeon, as a fee for surgical examination of his body after death.

BARTHOLOW'S "PRACTICE."—It has been stated that Bartholow's "Practice of Medicine" is being translated into Chinese for the benefit of the physicians of the Celestial empire.

INTESTINAL INDIGESTION.

By J. MILNER FOTHERGILL, M.D.,
LONDON, ENGLAND.

[ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.]

A PRACTICAL distinction may be drawn between gastric and intestinal dyspepsia; indeed, has been drawn between the two. In order to make this discrimination we follow the time of each part of the digestive act. When discomfort commences immediately after the introduction of food into the stomach, we regard the stomach as being the seat of the malady, as when there is a gastric ulcer present, for instance, or great irritability. When feelings of discomfort are quickly experienced, and after some time the food is vomited, little affected by the digestive act, and mixed with much mucus, then we suspect that there is gastric catarrh present, and that the food, rolled over and over by the muscular action of the walls of the stomach, becomes covered with a layer of mucus, through which the gastric juice cannot penetrate. The offending mass is at last rejected by vomiting, or is passed into the bowels and got rid of by purgation.

But at other times the symptoms complained of carry with them other interpretations. When there is little discomfort, either pain or flatulence, experienced until some considerable time after a meal, then we suspect the malady to lie rather in the duodenum and its relations, than in the stomach itself. For instance, a little time ago a gentleman from Ireland presented himself with this association of symptoms. He was over fifty years of age, strongly and broadly built, had lived well, even freely, and never knew anything of indigestion until within the last year or so. Since then he has had evidences of gouty indigestion with acid eructations, and considerable lithates in his urine. There is also some enlargement of his liver. But the significant symptom of all, to my mind, is this—his discomfort comes on from one to three hours after meals. Now we know as yet very little of the prodromata of cancer of the stomach before the familiar, well-recognized condition is established of pretty constant pain, little relieved by vomiting, acidity of the stomach, constipation, emaciation, with the development of the cancerous cachexia, and in time, especially when pyloric, the development of a tumor. There is, however, a stage anterior to this. Any one who has been able to keep a patient under observation for considerable periods knows how far from rare it is for chronic dyspeptics to die with unquestionable cancer of the stomach. Nor is it difficult to conceive that such should be the case—disturbances of function preceding organic changes; just as failure of functional power in the brain may pass away under appropriate measures; or, under other circumstances, pass on into that condition commonly spoken of as “softening of the brain,” that is, of organic change. Probably no one can always be sure what the resultant outcome of a distinct failure of brain-power may be. So with the stomach. A long history of functional disturbance culminates in organic disease. But when a well-nourished man, who has never known what it was “to have a stomach,” begins to suffer from acid dyspepsia, and has pain from one to three hours after a meal, then the suggestion of cancer of the pylorus forces itself upon one. Little relief had been afforded by the ordi-

nary bismuth mixture, and this was not without its significance. The case will be watched carefully to see what its further development may be.

The pylorus is in firm contraction for some time after a meal, so as not to allow the contents of the stomach to escape until fairly acted upon by the digestive fluid, and then it relaxes and allows the contents to escape into the duodenum. Why pain should be experienced until the ring relaxes is not quite clear; but the pain of pyloric cancer certainly is not particularly linked with the introduction of food into the stomach, as is that of gastric ulcer, and is not specially experienced when the ring is closed. As the case progresses the pain is more continuous; that is, when the ring is relaxed and contracted alike. Then there was the freedom from all gastric trouble till that time of life was reached when cancerous growths become common. There was, also, the negative results from appropriate treatment. The *tout ensemble* of the case was, to my mind, that of commencing cancer of the pylorus. The case was one of much interest; the more that a curious case of indigestion and vomiting, sometimes of blood, came indirectly under my notice some time ago, where opinions had varied, within narrow limits, and which turned out ultimately to be an ulcer situated within the pyloric ring itself.

More commonly pain with fulness is complained of from one to one-half hour or more after meals, *i.e.*, at the time when the food is passing out of the stomach into the duodenum, when we may fairly believe the following to be the case. Normally the acid contents of the bowel, when passing into the duodenum, are mixed with the alkaline bile to the extent not only of neutralizing their acidity, but of positively rendering them alkaline, so that the pancreatic fluid may be operative. But in those cases of duodenal dyspepsia it would seem that the alkaline tide from the liver is insufficient to perform this neutralization, and the pain and discomfort follow, the duodenum resenting the presence of an acid fluid. Whether this pain is due to this acid irritation solely, or there is muscular spasm set up thereby, may not yet be affirmed, the observations made so far being scarcely sufficiently minute. (The difficulty of making minute observations, when they have to be made through the medium of the patient's sensations, are self-apparent to any one.) When, however, the pain and discomfort come on at the time the food is passing into the duodenum, and are referred by the patient regionally to the duodenal area, and at the same time the stools are defective in bile, then duodenal dyspepsia is the probable cause of the symptoms. If, beyond this, a pill of ox-gall with castile soap, some two hours after a meal, is beneficial, and the addition of liquor pancreaticus sheathed by an alkali gives decided relief, then the diagnosis of duodenal dyspepsia is fairly established.

It would also be well to put the patient upon a dietary of farinaceous material and milk, so as to do away, to a great extent, with acid gastro-pepsin digestion, and develop alkaline intestinal trypsin digestion. The farinaceous material, with milk, might be guarded by some prepared chalk or calcined magnesia, to neutralize gastric acid digestion. By such means the acid condition of the duodenum is removed, and with it the discomfort. Milk sheathed with an alkali is just as much indicated in a case of duodenal dyspepsia as it is in the condition of gastric ulcer, where it is desirable to get the food through

the stomach with as little disturbance of that viscus as possible.

By the light of recent physiology such cases are beginning to be apparent, and it is possible to discriminate them, partly by their semeia, but still more by the effects of treatment. Duodenal dyspepsia is linked with those cases where fats are not assimilated, and where cod-liver oil passes the anus *en masse*. In such cases the ox-gall and castile soap, taken an hour or so after a meal, gives relief in time, and enables the oil to be emulsified, and after that to be taken up by the lacteals. This kind of case comes but comparatively little under the notice of the consultant, and it is to the observant family practitioner we must look for the record of these cases, and the effects of treatment. A sufficiency of cases only to furnish a strong surmise have come under the notice of the writer. If his readers will help by the publication of a few well-marked cases the diagnosis, and with it the rational treatment, duodenal dyspepsia will probably soon become a recognized matter.

Intestinal indigestion is also seen under other circumstances, viz., *lientery*. This word is old-fashioned, but is not obsolete. Here the food, but little changed by the digestive act, is voided per anus a brief while after being taken. The stomach passes the food into the intestines, and they sweep it along to the place of exit too speedily for any real digestion and absorption to take place. Lientery is found with children who may have had measles, with the low muco-enteritis which is apt to follow that exanthem, or in cases of mesenteric disease. Frequently large quantities of acid mucus are voided with the undigested food. Here alkalies with catechu or hematoxylin are indicated, with the inevitable milk dietary.

In tiny children an hyperæsthetic condition of the intestines is often seen, where the ordinary vermicular movements cause pain, the child crying the peculiar long abdominal wail, corresponding with the vermicular twist acting on the bowel, the seat of the muco-enteritis. The movements of the intestines may be felt through the thin abdominal walls, with or without flatulent distention. The stools smell sour. Here again alkalies are indicated, as prepared chalk with tincture of cardamom, or the bicarbonate of potash with cajeput oil; both useful combinations. Here the indications for treatment point to the neutralization of the acid formed in the intestine, together with the administration of a carminative of some kind (carminatives allay the energy of the intestinal peristalsis, and relieve painful vermicular action).

Such conditions are as much intestinal dyspepsia as they are anything else, as the digestive act is both painful and inefficient. It must be remembered that the different ferments of the pancreas are all alike only operative in an alkaline medium, and that in the presence of an acid they are inert. Consequently when the alimentary tract is acid, whether by acid formed in the stomach or formed below the stomach, or from the chyme being acid because the natural alkali in the bile is deficient, then the digestive ferments of the pancreas are killed and wasted. In the child, indeed, digestion is far more pancreatic than gastric; and such acidity of the bowel is very pernicious. When the acidity is greatest low down in the bowel it is well, as Prout pointed out, to use the fixed alkalies (chalk and calcined magnesia), which are not converted into soluble salts in the stomach, but which pass along the intestines and neutralize acid all along the alimentary tract. But such acidity is not confined to infants, and is seen in adults. The question of how far a little mercurial, especially as gray-powder, is useful in such conditions of acidity may be raised. Some authorities are in favor of such medication, and certainly in those cases where the acidity appears due to deficiency of the alkaline salts of the bile, it would recommend itself. Of course, with very delicate children, not being congenitally syphilitic, caution is requisite in prescribing mercurials; but at the present day the caution is so excessive that mercury is avoided altogether by some practitioners.

To eschew mercurials altogether is fanaticism, therapeutic fanaticism, nothing more.

There are other conditions of intestinal dyspepsia less commonly encountered, which may just be alluded to. In a case of confirmed indigestion, due to long sustained overwork in establishing a commercial enterprise in Russia, which came under notice lately, the discomfort was referred to the transverse colon, and was mainly experienced about three hours after a meal. Sweet things and sour things, all seasoning whatever, were an offence; while, as the patient said, "I don't eat enough to nourish me, and if I did, I should not digest it!" His complaint was a just one. However, he did improve sufficiently to revisit Russia; but at Kief he caught dysentery, and just managed to get back to England before being completely prostrated. The attack was not a severe one, for a healthy person at least, and there was no thickening of the colon, that either Sir Joseph Fayrer or myself could detect; but the uncomfortable sensations referred to the transverse colon were very troublesome, and being about persistently. Gradually they declined, and now the patient is again making headway, still having to be very particular about his dietary. If such cases scarcely fall under the heading "indigestion," they do, however, come under the heading "dyspepsia," and they require a most careful dietary. In this particular case small quantities of liver-stimulants only were required, as much bile in the fæces irritated the bowel not a little.

Cases like this may easily be mistaken for gastric indigestion, if the observation as to the time after a meal when the discomfort is experienced be not properly made. In my former article on "Atonic Dyspepsia," the methods of treating primary gastric indigestion were laid down. Here it may be said that the liver requires to be roused, and bile supplied to the chyme, either by increasing the flow from the liver, or by giving ox-gall in pill, either with or without castile soap, until a sufficient natural flow is secured. By such means, and by the exhibition of liquor pancreaticus and fixed alkalies much may be done for those cases of dyspepsia which lie below the pyloric ring; in other words, for dyspepsia in the alkaline area of the alimentary canal. How far the pancreas can be stimulated by either, as first suggested by Balthazar Foster, and approved by a Medical Commission in the United States Army, in cases where the assimilation of fat is deficient, is a matter of practice which calls for more attention. But by the use of hepatic stimulants, which includes the rational resort to mercury, alkalies, and artificial pancreatic secretion, and an appropriate dietary, much may be done where intestinal digestion is painful or is imperfect. The main thing to be done is to discriminate what is amiss, and then how may it be remedied. For both, perfect familiarity with the digestive act, its divisions, and the time after taking food when each occurs, is absolutely requisite. When it is found out where the difficulty occurs then the appropriate measures can be adopted. And it may be the symptoms are not experienced in the abdomen at all when the malady lies below the pylorus. When imperfectly digested products are poured into the portal circulation the main complaint may be psychical, as lowness of spirits, oppression, or panphobia, occurring two or three hours after a meal. Or may be lithates are freely formed, and, in some cases, irritability and discomfort in the urinary passages are set up as soon as these mal-products reach the bladder. In such cases alkalies with some pancreatic preparation will often give much relief, especially if at the same time the dietary be strictly regulated; and hepatic stimulants are certainly of service.

DR. CHARLES FREMONT DIGHT, assistant to the Chair of Pathology and Practice of Medicine in the University of Michigan, has been elected Professor of Anatomy and Physiology in the Medical College at Beirut, Syria, Asia.

ON THE PECULIAR APPEARANCE OF THE INITIAL LESION OF SYPHILIS AT THE EARLIEST PERIOD OF ITS DEVELOPMENT.¹

BY R. W. TAYLOR, M.D.,

SURGEON TO CHARITY HOSPITAL, NEW YORK; PROFESSOR OF VENEREAL AND SKIN DISEASES IN THE UNIVERSITY OF VERMONT.

THE importance of the early recognition of the initial lesion of syphilis is so great that any facts tending to enlighten us in this direction are of more than ordinary value. In the *American Journal of Syphilography and Dermatology* for July, 1871, I published the description of the appearance of an initial lesion of syphilis, as observed on the first day of its evolution. These appearances were such that scarcely any one would have suspected that the seemingly insignificant spot was really the starting-point of syphilitic infection.

From that date until May, of this year, I had not met with a similar case, but at that time a second one came to my notice. I shall, therefore, give the details of these two cases, which present clearly marked features of the hard chancre, which had also been observed years ago by my friend the late Professor William Boeck, of Christiania, as he informed me in an oral communication, but which have not, I believe, until now, been described by any one but myself. In connection with the description of this peculiar appearance of the hard chancre at its earliest period of evolution I will try to present the other appearances which it usually presents, since by this course more completeness to the general picture is gained. In addition, I shall speak briefly of the appearance of the initial lesion of syphilis in children in its very earliest days. The first case is transcribed nearly verbatim from the journal before mentioned.

M. M—, a native of Poland, came to the New York Dispensary, January 17, 1870, and presented a peculiar lesion on the penis. Upon the inner aspect of the right lip of the meatus urinarius was a spot about the size of the heads of two pins, which presented a silvery appearance. The spot was not at all elevated, but directly continuous, without any elevation or fissure with the surrounding membrane, and there was no fissure, however slight, to be seen through the spot itself, even with the aid of a magnifying-glass. I thought that perhaps the man had cauterized it with nitrate of silver, but he declared that he had not interfered with it at all. He stated that he had for the first time observed the spot that morning. It was evident that the lesion consisted in some change produced in the superficial epithelial cells of the part. Professor W. Boeck, of Christiania, being present at the examination, remarked that he had seen the initial lesion of syphilis once or twice before begin in this manner upon the penis, and that he had often observed it to commence in this way in the mouths of children. In two succeeding days the area of the silvery patch increased very little, and in four days a small amount of induration could be distinctly felt, since the parts were so accessible to careful manipulation. In a week a distinctly marked indurated nodule was formed, which very much everted the lips of the meatus. The inguinal ganglia had by this time become perceptibly hard and swollen. When the nodule, which though no larger than a small pea, but which was very firm in consistence, had existed about a week, the epithelial scales which covered it were cast off, and a very slightly grayish exulcerated surface was observed, the granulations of which were very small, and it was covered with a very scant viscid secretion. This indurated ulcer remained in a sluggish condition for six weeks, when a roseola erythema of fauces and general malaise supervened, which were treated by mercury and disappeared quite rapidly. For two years the man had various lesions, but owing to persistence in treatment he was cured, and has since been well.

On May 20, 1883, a gentleman, who shall be nameless,

came to me in great anxiety and fear regarding a suspicious connection he had had the night before. He was a man forty-four years of age, who since his marriage, twenty years previously, had had no intercourse with strange women, and had been true to his wife. His recollection of the night previous was a hearty dinner and much champagne; and in the morning he awoke in a brothel in the arms of an aged siren. Though assured most solemnly by this woman that she had no disease, he became greatly worried and sought me to determine whether he had contracted any venereal trouble. I frankly stated his probable dangers in gonorrhœa, chancre, and syphilis. So great was his anxiety that he came to me for examination every day, and suffice it to say he did not contract the two local forms of contagion. On the twelfth day, absolutely nothing abnormal having been observed on his penis up to that time, I saw a small oval spot of a glistening silvery appearance on the dorsum of the glans penis midway between the meatus and the balano-preputial furrow. This small spot was of about the size of three small pin-heads, and was distinctly visible at all times, since the prepuce was very small and barely covered the base of the glans. Recalling my experience with the afore-described case, I informed the gentleman that he had very probably contracted syphilis, and that his domestic quarantine must still be rigidly followed for fear of infecting his wife. The patient's fears were such that I had almost daily opportunity to observe the development of this lesion. Its course was briefly as follows: The silvery spot increased in area slowly. Its surface was perfectly unbroken, and during its early days it could be distinctly seen that the morbid process was superficial and confined to the epithelial layer; moreover, there was no circumferential hyperæmia. Thus increasing, at the end of ten days the spot occupied an area of a line in diameter, and was round. From this time on deeper changes were observed, thickening of the uppermost layers of the mucous membrane was distinguishable in about fifteen days, and sharply marked parchment induration was clearly felt on the twentieth day. Swelling of the inguinal ganglia was discovered on the eleventh day. The silvery appearance of the nodule was well marked until about the fifteenth day, at which time it might have been mistaken for a papule of lichen planus. From this date onward the silvery gloss grew less, redness appeared over the surface, and in twenty days from its appearance the chancre was typical in its appearance—a smooth exulcerated surface, sharply defined margin, and an abrupt elevation. On July 13th, an erythematous syphilide came out over the epigastrium and abdomen, and in a week it covered the whole body.

The point of interest of these cases consists in the peculiar, localized, silvery appearance of the mucous membrane of the glans penis, which were soon to be the site of the true Hunterian chancre. The importance of the early recognition of the nature of this lesion is well shown in this case, since it is very probable that a person who had never before seen it, would have regarded it as insignificant, and would not have prevented the gentleman having intercourse with his wife. The practical conclusion is this, that at its evolution the initial lesion of syphilis may appear simply as a small, unelevated, silvery spot, seated in the mucous membrane, without any inflammatory areola. This spot may thus remain superficial and free from ulceration and induration for nearly two weeks, after which time, and even before, it may increase in development and assume the appearances of a typical indurated chancre. In this connection I may add that there are two other appearances presented by the initial lesion of syphilis at its earliest period. The first appears simply as a minute, sharply rounded, excoriated spot, the surface of which is neither elevated nor depressed, and appears like a most superficial erosion of the epithelial cells of the mucous membrane. Generally these spots are of a sombre red color, which later on may become

¹ Read before the American Dermatological Association, at Lake George, August 30, 1883.]

coppery red, and usually are not the seat of hyperæmia. Their future course is one of extension on the surface and in depth. In somewhat rare instances numbers of these spots, from three to as many as a dozen, may appear, and then we have the multiple herpetic form of chancre of Dubuc. The third and last of the earliest appearances of the initial lesion of syphilis is in the form of a small, slightly elevated papule, having a dry unbroken surface. This form of chancre, the *papule sèche* of Lancereaux, is mostly seen in persons having short prepuces, and in those who have none, or but the rudiment of one. It begins in this subacute, indolent, and insidious manner, and may run its whole course without any ulceration or excoriation, or it may follow the course of the indurated nodule, or become transformed into the parchment-like chancre.

It is needless to add that it is important to bear these peculiar appearances in mind, as by so doing and by acting on the warning given by them, much misery may be spared.

In this connection I may add that I have several times in my life confirmed the statement of Professor Boeck, to the effect that in children the initial lesion often begins as a very minute, shining, and silvery spot, similar to those just now described. I well remember an instance of a child, infected by its wet nurse, at the tip of whose tongue, a little to the right side, was a minute linear spot, which appeared as if cauterized by the pencil of nitrate of silver, and which went on to form a large indurate nodule, which was followed by syphilis. Also I can now picture in my mind a small spot, such as I have now fully described, on the lower lip of an infant, which later on became an enormous Hunterian chancre. The practical indications of these facts are obvious.

OBSERVATIONS ON THE ACTION OF NEW REMEDIES.

By W. S. GOTTHEIL, M.D.,
NEW YORK.

IN December, 1882, at the suggestion of my visiting physician, Dr. J. J. Reid, I began a series of observations on the therapeutic results obtainable from certain drugs, to which professional attention has more recently been drawn. As House Physician of the second medical division at Charity Hospital, a large field for study was open to me, and considerably over one hundred cases were recorded. These experiments lasted from December 1, 1882, to April 1, 1883, and were made with the following drugs:

1. Convallaria maialis, fluid extract.
2. Manaca, fluid extract.
3. Eucalyptol.
4. Yerba santa, fluid extract.
5. Chekan, fluid extract.
6. Ol. gaultheriæ (in rheumatism).
7. Lippia Mexicana, fluid extract.
8. Quebracho, fluid extract.

The first one of the list, the lily of the valley, is the most important, and at the present moment far the most interesting one of the series. I shall therefore give, in somewhat fuller detail, the account of the results obtained with it.

1. *Convallaria*.—The cases treated with this drug numbered fifteen in all, there being nine cases of organic heart disease, five cases of cardiac failure from various causes, and one case of Bright's disease. The preparation used was the fluid extract.

CASE I.—Hannah B.—, aged forty-three; mitral regurgitation, marked hypertrophy, and probably dilatation, dizziness, pain and palpitation very marked; pulse, 84, very irregular, both in force and frequency; respiration, 48; temperature, 98½°. January 20th: Convallaria, fluid extract, gtt. x. t. i. d. January 24th: Pulse about 90, but so irregular as to be almost uncountable; pains

same; occasional attacks of cardiac asthma; convallaria, gtt. xx. t. i. d. January 27th: Pulse, 105; no improvement; convallaria stopped; ordered tr. dig. gtt. v. t. i. d. January 31st: Pulse, 84; unimproved; tr. dig. gtt. x. t. i. d. February 10th: Somewhat easier; pulse, 96; same. February 21st: Pulse, 90, still as irregular; tr. dig. gtt. xv. t. i. d. February 25th: Slight improvement in palpitation and pain; pulse 84, same; digitalis stopped; ordered convallaria, gtt. xx. t. i. d. February 28th: Pulse, 90, less irregular; convallaria, gtt. xxx. t. i. d. March 2d: Pulse, 75. March 4th: Heart rhythm no better; palpitation and pain much relieved; convallaria, gtt. xl. t. i. d. March 5th: Pulse, 96, irregular; convallaria, 3 i. t. i. d. March 7th: Pulse, 90, same. March 10th: Pulse, 90, unimproved; convallaria stopped.

CASE II.—Justin McC.—, aged fifty-two; mitral regurgitation; pulse, 84, irregular in force, feeble, occasionally intense; dilatation. February 28th: Attacks of dizziness; convallaria, gtt. v. t. i. d. March 2d: Pulse, 66, stronger, still irregular. March 5th: Pulse, 60; dizziness better; convallaria, gtt. x. t. i. d. March 6th: Pulse, 60, as irregular as ever; general condition—pain, dizziness, etc.—much improved. March 8th: Discharged at request.

CASE III.—John J. D.—, aged thirty-one; mitral obstruction, cardiac hypertrophy; cardiac beat irregular in force and frequency; palpitation, dyspnoea, etc.; pulse, 120. January 25th: Convallaria, gtt. x. t. i. d. January 29th: Pulse less irregular, but just as frequent; convallaria, gtt. xv. t. i. d. February 1st: Pulse, 120, irregular; feels better; palpitation somewhat less; convallaria, gtt. xxx. t. i. d. February 5th: Pulse, 78, irregular in force and frequency. February 8th: Pulse, 96; much more comfortable; palpitation much improved; no dyspnoea; can go up and down stairs easily. February 22d: Discharged, in fair condition.

CASE IV.—Alexander McM.—, aged twenty-three; mitral regurgitation and aortic obstruction; considerable hypertrophy, dyspnoea, palpitation, pain, cough, and blood-streaked sputum; pulse, 80, regular, fairly strong. January 15th: Convallaria, gtt. v. t. i. d. January 19th: Considerable dyspnoea and pain; phlegm blood-streaked; pulse, 72; convallaria, gtt. x. t. i. d. January 23d: Same; convallaria, gtt. xx. t. i. d. January 26th: Pain considerably better; palpitation and dyspnoea as before; convallaria, gtt. xxx. t. i. d. January 30th: Pulse, 72; condition same. February 2d: Pulse, 72; symptoms no better. February 6th: Pulse, 84; convallaria, 3 i. t. i. d. February 8th: Pulse, 72; precordial pain undoubtedly better, but otherwise no change. Treatment stopped.

CASE V.—Patrick H.—, aged twenty-four; mitral regurgitation and aortic obstruction; hypertrophy; much precordial pain; pulse, 90, and rather feeble; dyspnoea, but especially palpitation and pain. February 27th: Convallaria, gtt. x. t. i. d. February 28th: Pulse, 84; somewhat better; dyspnoea and palpitation as before; convallaria, gtt. xx. t. i. d. March 2d: Breathing better, and steadily improving; less palpitation; pulse, 96, fairly strong; convallaria, gtt. xxx. t. i. d. March 3d: Pains in side began again; pulse, 90; convallaria, gtt. xl. t. i. d. March 5th: Much precordial pain; palpitation undoubtedly less; pulse, 90, small and hard; convallaria, 3 i. t. i. d. March 6th: Pulse, 80, much improved, full and strong; little pain. March 7th: Pulse, 90, good; general condition fair; no pain. Discharged at request.

CASE VI.—Patrick E.—, aged fifty-six; mitral regurgitation and aortic obstruction; but little hypertrophy; headache; feet slightly swollen; urine negative; pulse, 120, feeble. January 22d: Convallaria, gtt. v. t. i. d. January 29th: Pulse, 120, fuller; headache; swelling gone down; much cough; convallaria, gtt. x. t. i. d. February 1st: Pulse, 132; headache bad; convallaria, gtt. xx. t. i. d. February 6th: Pulse, 96, much improved in tone; headache and tightness in head; convallaria stopped.

CASE VII.—Rose McG—, aged thirty-six; mitral stenosis and insufficiency, aortic stenosis, dilatation, great dyspnoea, and palpitation; feet slightly swollen; urine negative; pulse, 108, irregular and intermittent; fluttering and oppression around heart. Treated with digitalis, caffeine, etc., with slight result. January 18th: Pulse, 100, irregular; convallaria, gtt. x. t. i. d. January 20: pulse, 66, fuller, but irregular; fluttering somewhat better; convallaria, gtt. xx. t. i. d. January 24th: Pulse, 86, fair; feels better; fluttering less; can rest better at night; convallaria, gtt. xxv. t. i. d. January 27th: Pulse, same, still irregular. February 10th: Pulse, 84, fairly good, irregularity of beat quite unaffected; little dyspnoea or palpitation; convallaria stopped.

CASE VIII.—Theresa K—; mitral regurgitation; mitral stenosis; aortic stenosis; dilatation; palpitation; dyspnoea; cardiac pain; severe dyspnoea in spells; cough; phthisis, second stage, etc.; pulse, 108, moderately strong. January 20, 1883; Convallaria, gtt. xv. t. i. d. January 22d: Feels very bad; breathing labored; violent palpitation; much dyspnoea and pain inside; pulse, 120, small; convallaria, gtt. xxx. t. i. d. January 23d: Pulse, 113, small. January 24th: Pulse, 108, slightly stronger; slightly nauseated by drops; convallaria, gtt. l. t. i. d. in milk and lime-water. January 27th: Pulse, 108, improving; cardiac distress unaffected; vomited several times last night. Convallaria stopped; ordered cerii oxalas, gr. xx. t. i. d. January 29th: Vomiting better; pulse, 104, small; dyspnoea, palpitation, pain, as before; convallaria, 3i. t. i. d. January 31st: Negative result; dyspnoea very bad; convallaria, 3ij. t. i. d. February 1st: Nauseated again, the palpitation, dyspnoea, and precordial pain entirely unaffected; convallaria stopped.

CASE IX.—Charles S—, aged forty-two; mitral regurgitation, aortic stenosis, and aortic regurgitation; hypertrophy; dyspnoea marked. January 26th: Pulse, 84, small and jerking; convallaria, gtt. xx. t. i. d. January 30th: Pulse, 78, regular; dyspnoea and pain unimproved; convallaria, gtt. xl. t. i. d. February 2d: Pulse, 84; but little improvement; convallaria, 3i. t. i. d. February 6th: Pulse, 108, fuller and stronger than before; precordial pain somewhat less; no change in dyspnoea and palpitation. February 8th: Little result from convallaria, ordered stopped; tinct. dig. gtt. x. t. i. d. February 9th: Less pain; pulse, 84; tinct. dig. gtt. xx. t. i. d. February 16th: Pulse, 72; dyspnoea marked; tinct. dig. gtt. xxx. t. i. d. February 23d: Statu quo; dig. reduced to gtt. xx. t. i. d. February 27th: Pulse, 78, much feebler; is a good deal better, but still complains of dyspnoea; dig. stopped; convallaria, gtt. xv. t. i. d. March 2d: Same; convallaria, gtt. xxv. t. i. d. March 5th: Less dyspnoea and palpitation than at any time since entrance; convallaria, gtt. xxxv. t. i. d. March 7th: Improvement marked; his heart gives the man but little trouble. Transferred to convalescent help.

CASE X.—Charles N—, aged sixty-five; Bright's disease; oedema of feet and legs; nausea, vomiting; moderate dyspnoea; considerable cough; cardiac signs negative; lungs, emphysema and chronic bronchitis; urine, average daily amount twelve to twenty-five ounces; moderate amount of albumen, hyaline and granular casts. January 18th: Urine, twenty-one ounces; elimination by skin and bowels with slight result. January 22d: Getting steadily worse; urine, twelve ounces. January 23d: Pulse, very rapid and irregular; convallaria, gtt. xv. t. i. d. January 24th: Pulse is uncountable at wrist; urine, fourteen ounces; oedema very painful, punctured and bandaged; convallaria, gtt. xxx. t. i. d.; heart-beat, 108. January 26th: Urine, seventeen ounces; somewhat easier; pulse, 100. Patient died January 27th.

CASE XI.—Lizzie H—, aged twenty-eight; phthisis, second stage; much enfeebled by successive hæmoptyses. February 23d: Pulse, 96, very small indeed; convallaria, gtt. x. t. i. d. February 25th: Pulse, 118, somewhat

stronger; convallaria, gtt. xv. t. i. d. February 28th: Rapidly improving; pulse, 96, still feeble; convallaria, gtt. xxx. t. i. d. March 3d: General condition satisfactory; pulse considerably stronger, 102. March 10th: No further results. Patient discharged at request.

CASE XII.—Constantine Z—, aged thirty-two; acute articular rheumatism; no pericardiac or cardiac lesion; convalescence; pulse almost imperceptible, and varying for days between 114 and 160; temperature normal. Digitalis and ordinary cardiac tonics tried—no result. January 15th: Pulse, 130; temperature and respiration normal; convallaria, gtt. v. t. i. d. January 16th: Pulse, 140. January 17th: Pulse, 156; convallaria, gtt. x. t. i. d. January 18th: Pulse, 140, very feeble; convallaria, gtt. xv. t. i. d. January 19th: Pulse, 120, somewhat stronger; convallaria, gtt. xxv. t. i. d. January 20th: Pulse, 102; undoubtedly better and stronger. January 22d: Pulse, 90, regular and full; convallaria, gtt. xxx. t. i. d. January 23d: Pulse, 78, good. January 25th: Pulse, 80. January 26: Pulse, 108, and slightly weaker; convallaria, gtt. xl. t. i. d. January 27th: Pulse, 80, fair; convallaria, 3i. t. i. d. January 30th: Pulse, 102, regular and good. February 1st: Pulse, 80. Discharged.

CASE XIII.—Henry H—, aged thirty-eight; melancholia; excessive feebleness of heart-beat; no physical lesion or symptom; pulse, 96–108. January 23d: Convallaria, gtt. xv. t. i. d. January 25th: Pulse, 80, much fuller and stronger; convallaria, gtt. xx. t. i. d. January 30th: Pulse, 90, excellent; convallaria, gtt. xxx. t. i. d. February 2d: Pulse, 84, full and strong; no other effect.

CASE XIV.—John R—, aged fifty; acute alcoholism; very shaky; pulse, 77, exceedingly feeble, almost imperceptible at the wrist; first sound of heart hardly audible with a stethoscope. January 23d: Convallaria, gtt. xx. t. i. d. January 25th: Pulse, 72, same; convallaria, gtt. xxx. t. i. d. January 26th: Pulse, 80, slightly better; convallaria, gtt. xl. t. i. d. January 27th: Pulse, 60, not improved at all to day; convallaria, 3i. t. i. d. January 30th: Pulse, 60, very feeble indeed; convallaria stopped.

CASE XV.—James S—, aged forty-eight; phthisis, third stage; very serious hæmoptysis; pulse, 66, very feeble, hardly perceptible at the wrist. January 15th: Temperature, 98½°; respiration, 30; convallaria, gtt. x. t. i. d. January 17th: Pulse, 80, improving; feels stronger; no more blood in sputum. January 19th: Pulse, 96, much stronger. January 22d: Patient had another severe hemorrhage; pulse, 66, very feeble. January 23d: Pulse, 72, almost imperceptible; convallaria, gtt. xx. t. i. d. January 24th: Pulse, 70; respiration, 24; temperature, 99°; pulse still very feeble; convallaria, gtt. xxxv. t. i. d. January 26th: Some improvement; convallaria stopped and other treatment resorted to.

And now a brief résumé of results: There were nine cases of organic heart disease, in most of which considerable hypertrophy had already occurred, or dilatation had even taken place. In six of these cases a moderate effect was obtained from the remedy; in three there was no result. In none of the cases in which irregularity or intermittency of the pulse was marked did convallaria affect the heart-rhythm. It has been claimed that convallaria is more adapted for cases of functional than for cases of organic heart disease; but the amount of relief which some of the above cases obtained was very considerable, and I cannot but look upon the drug as an occasionally valuable agent even in the most advanced forms of cardiac disease. The results obtained in the remaining six cases were not much better than those from the first nine. Five of these cases were cases of cardiac failure from acute disease, from hemorrhage, or from depraved general conditions. Of these five, one only was not benefited at all; and in several cases the results were very satisfactory.

I found it necessary, however, in most cases, to give

doses considerably in excess of the ordinary ones. Several cases took $\mathfrak{z}$ i. of the fluid extract t. i. d. without bad effect; one case, No. VIII., took $\mathfrak{z}$ ij. t. i. d., and was nauseated by it; but the patient had been suffering from chronic gastro-catarrh before, and it is possibly unfair to attribute her vomiting to the drug alone.

One word as regards the diuretic effects of convallaria. I am sorry that I did not have the urine measured in all the cases from day to day. In the only case in which that was done, No. X.—one of advanced disease of the kidneys—the amount of urine was not increased, and the dropsy was not affected. But there was certainly no very marked diuresis caused by the drug in any case, for it would surely have been brought to my notice.

2. *Manaca*.—Twelve cases were treated with this drug—all cases of chronic rheumatism. In the cases which were benefited the heat and swelling rapidly disappeared from the joints; the pain on motion of the limb and consequent disability soon became better. In almost all cases I began with the usually prescribed dose—five, ten, fifteen drops—but was obliged to increase it to two drachms, or half an ounce, before any decided effect was observed. The preparation used was the fluid extract prepared by Parke, Davis & Co.

CASE I.—Chronic rheumatism. Dose, $\mathfrak{z}$ i. to $\mathfrak{z}$ ij. t. i. d. Began to improve on fourth day; under treatment one month; recovered completely.

CASE II.—Chronic rheumatism. Dose, $\mathfrak{z}$ ss. t. i. d. Began to improve on sixth day; under treatment thirteen days.

CASE III.—Chronic rheumatism. Dose, $\mathfrak{z}$ i. t. i. d. No result; under treatment nine days.

CASE IV.—Chronic rheumatism. Dose, $\mathfrak{z}$ i. t. i. d. No result; under treatment sixteen days.

CASE V.—Chronic rheumatism. Dose, $\mathfrak{z}$ ij. t. i. d. Began to improve in three days; good result; whole time of treatment eleven days.

CASE VI.—Chronic rheumatism. Dose, $\mathfrak{z}$ ss. t. i. d. No result; under treatment ten days.

CASE VII.—Chronic rheumatism. Dose, $\mathfrak{z}$ ij. every four hours. No improvement at all; under treatment five days.

CASE VIII.—Chronic rheumatism. Dose, $\mathfrak{z}$ ij. t. i. d. Improvement began in five days; good results; time of treatment fourteen days.

CASE IX.—Chronic rheumatism. Dose, $\mathfrak{z}$ ss. t. i. d. Began to improve in three days; good result; time of treatment eight days.

CASE X.—Chronic rheumatism. Dose, $\mathfrak{z}$ ij. t. i. d. Joints began to get better in five days; time of treatment twenty-four days; very good result.

CASE XI.—Chronic rheumatism. Dose, $\mathfrak{z}$ ij. t. i. d. Improvement began in two days; excellent result; time of treatment eighteen days.

CASE XII.—Chronic rheumatism. Dose, $\mathfrak{z}$ ij. to $\mathfrak{z}$ ss. t. i. d. Improvement began on third day and continued to a certain extent, and then stopped.

Of the twelve cases of chronic rheumatism, seven received very marked benefit from the drug; one was moderately relieved, and in four cases no effect at all was perceived. I regard the drug as certainly worth a trial, at least in these very common and often very troublesome cases.

3. *Eucalyptol*.—My attention was drawn to the use of eucalyptol in cases of phthisis, chronic bronchitis, etc., by a writer in the *Berl. Klin. Wochenschr.* of last year, who recommended it both internally and by inhalation in these cases. Fifteen cases in all were observed; Merck's preparation of the drug was used. It was claimed that it lessened the cough and expectoration, diminished fetor, etc.

CASE I.—Phthisis, third stage. Dose, gtt. x. t. i. d., and inhaled. Relief began on second day, and continued sixteen days, as long as drug was continued.

CASE II.—Phthisis, second stage. Dose, gtt. v. t. i. d. No effect at all; took eucalyptol seven days.

CASE III.—Phthisis, second stage. Dose, gtt. v. t. i. d. Improvement began on second day, and continued until her discharge—six weeks.

CASE IV.—Phthisis, third stage. Dose, gtt. v.—xv. t. i. d. Relief began in five days, and continued to a moderate degree during the two weeks of treatment.

CASE V.—Phthisis, second stage. Dose, gtt. v. t. i. d. Relief began on third day, and continued till she was transferred, three weeks later.

CASE VI.—Phthisis, third stage. Dose, gtt. v.—x. t. i. d. No result at all. Took eucalyptol seventeen days.

CASE VII.—Asthma and chronic bronchitis. Dose, gtt. v.—x. t. i. d. Relief began in two days, and continued during time of treatment—one week.

CASE VIII.—Phthisis, second stage. Dose, gtt. x. t. i. d. Relief in two days; continued for two weeks.

CASE IX.—Phthisis, third stage. Dose, gtt. x.—xxx. t. i. d. No result. Took eucalyptol for ten days.

CASE X.—Phthisis, third stage. Dose, gtt. x.—xxx. t. i. d. No improvement at all. Took eucalyptol two weeks.

CASE XI.—Phthisis, third stage. Dose, gtt. v.—xx. t. i. d. No effect till he had taken drug a week; then began to improve, and continued doing so during remaining time—two weeks.

CASE XII.—Phthisis, third stage. Dose, gtt. v.—xx. t. i. d. Began to improve in three days, but drug soon lost all effect.

CASE XIII.—Phthisis, second stage. Dose, gtt. v.—xx. t. i. d. Began to be relieved by second day; continued so for two weeks, and then drug lost its effect.

CASE XIV.—Phthisis, second stage. Dose, gtt. x. t. i. d. No result. Took drug for ten days.

CASE XV.—Phthisis, third stage. Dose, gtt. v.—xxx. t. i. d. No result from encalyptol. Treated two weeks.

Fifteen cases, then, in only four of which the patient was distinctly benefited. Four cases were relieved to a small extent, and seven cases were not affected at all. Still the cases that did well under it obtained marked relief. It seems to be of most use in cases with very abundant muco-purulent expectoration.

The inhalation of the vapor from a respirator containing a sponge upon which a few drops of eucalyptol can be poured is undoubtedly a valuable method of administration of the drug.

4. *Yerba Santa*.—A large number of cases were treated with this drug, which has been much vaunted as a stimulating expectorant. There were 41 cases observed in all, 30 of them cases of phthisis, second and third stages, and the rest bronchitis with asthma and emphysema, Bright's disease, etc. I cannot say that the results have been in any way encouraging. In only 9 cases was any real benefit observed; in 11 a moderate amount of relief was obtained; 21 cases were not affected at all. Nay, more than that, in a very large number of cases—17 in all—gastric derangement, nausea, and vomiting were caused by the drug. I cannot, therefore, look upon yerba santa as a very important addition to our list of expectorants.

5. *Chekau*.—This drug belongs to about the same class as the one last considered, and can hardly be looked upon as of much more value. Twenty-one cases were treated with it, most of them cases of chronic cough from phthisis, bronchitis, etc. In only 8 cases was marked relief in the cough and expectoration afforded by the drug; in 2 or 3 a slight effect was noted; in the remaining 11 cases there was no result at all. In 3 cases the medicine disagreed, caused nausea and vomiting, and had to be stopped. The fluid extract was the preparation used, and the dose one drachm to half an ounce t. i. d. Here, then, is a result which is hardly more encouraging than that obtained with yerba santa.

6. *Oleum Gaultherie*.—This drug was carefully tried in four cases of severe subacute rheumatism with moderate success. The doses used varied from five to ten drops three or four times a day, and no other treatment what-

soever was employed. In all four cases much relief was obtained from the drug; in all of them the swelling, the pain, and the local heat soon diminished, and the patients were shortly convalescent; but in every case, also, a certain amount of disability was left which the drug did not relieve, and for which recourse had to be had to frictions, massage, etc.

7. *Lippia Mexicana*.—Twelve cases were treated with this expectorant, of which the fluid extract was given in half-drachm to half-ounce doses t. i. d. A somewhat better result was obtained than was done with the other two expectorants tried. In seven cases out of the twelve the harassing cough was markedly relieved, enabling patients to obtain a comfortable night's rest who had previously been able to get it only by a free use of narcotics. Five cases were not affected at all; but in no case was there seen the disagreeable gastric disturbances caused both by yerba santa and chekau. I look upon it, therefore, as a remedy of some value for the relief of an often very distressing symptom.

8. *Quebracho*.—Excellent results were obtained with the fluid extract of this drug. Nine cases were observed, and in all of them save one great relief was obtained from the dyspnoea. The cases comprised ones of asthma, valvular cardiac disease, Bright's disease, chronic bronchitis, and phthisis, and in all but one case of phthisis respiration became easier, the blueness disappeared from the finger-ends and the prolabia, and the patient's general condition became very much better. The doses used were half a drachm to two drachms t. i. d.

A CONTRIBUTION IN FAVOR OF COTTAGE HOSPITALS—REPORT OF TWO INTERESTING SURGICAL CASES.

By W. L. ESTES, M.D.,

MEDICAL SUPERINTENDENT OF ST. LUKE'S HOSPITAL, SOUTH BETHLEHEM, PA.

THE essay on "Cottage Hospitals," published by Dr. Burdett, excited so much interest in this country, and these enterprises or charities were so highly advocated generally by our medical press, that the following short statistical report of the one of which the writer has charge may prove of interest to the profession, and is given for what it may be worth.

St. Luke's Hospital, situated in South Bethlehem, was opened in 1873. The first year 69 patients were treated. Last year, 1881-82, 692 patients received treatment. Beginning in an ordinary two-story brick cottage, it is now grown to the dimensions of a brick pavilion (opened only last year), built upon the most approved modern pavilion hospital plan, and possessing every convenience of a metropolitan hospital, also two wooden buildings after the ordinary country style of architecture, having an aggregate capacity of forty beds. The pavilion has two wards, of twelve beds each, and is used for acute surgical cases; one wooden building, having a capacity of eight beds, for women's diseases; and the other wooden building, with eight beds, for isolation. Since the opening of the pavilion, from November 21, 1881, to November 21, 1882, there have been 43¹ major operations performed, with 2 deaths, or 4.8 per cent. The operations were, 20 major operations, with 2 deaths; 9 major excisions, with no death. The remaining 14 were miscellaneous, and no fatal result.

The amputations were as follows: 1 at wrist-joint, recovered; 2 of forearm, both recovered; 3 of arm, all recovered; 8 of leg, 1 death; 2 at knee-joint, both recovered; 3 of thigh, 1 death; 1 at hip-joint, recovered. Total, 20 cases, 2 deaths.

The death after amputation of the leg was from delirium

tremens on the tenth day; that after amputation of the thigh, from septicæmia. The amputation was done for compound comminuted fracture of the leg after a prolonged attempt had been made to save the limb. The patient was already suffering from septicæmia when operated upon. He never rallied from the condition, and died about twelve days after the amputation.

The resections were: 2 of tarsus, 2 of tibia, 1 of knee-joint, 2 of femur, 1 of hip-joint,¹ 1 of ribs (for empyæma); all recovered. Total, 9 cases, 9 recoveries.

Of the amputations 2 were done for diseased conditions. The hip-joint amputations; 18 were after injuries. Of these, 15 were primary or immediate, and 3 were secondary or intermediate (done during active inflammation and suppuration). With scarcely a single exception, in every case of amputation from injury, there had been excessive hemorrhage before the patient arrived at the hospital.

Except the resection of the knee-joint all of the excisions were for diseased joints and bones. In all these cases the modified Lister dressing was employed, that is to say, thorough cleansing of the limb at the seat of operation, disinfection of the skin and wound—if there was one—with five per cent. solution of carbolic acid; hands of operators and assistants disinfected with the same solution, as were the sponges, instruments, etc., used during the operation. Afterward a full Lister dressing was applied, and removed only when soiled or the temperature of the patient rose. In the whole series of cases there was not a single case of gangrene, nor of osteomyelitis, nor phlebitis, nor erysipelas. Not a single case of secondary hemorrhage. The average time in the hospital was 28.3 days.

Among the operations there are two which appear to be of sufficient interest to publish.

CASE I.—George R—, nine years of age, admitted February 6th. Five months before admission the patient was struck by a locomotive, and besides severe internal injuries, sustained a fracture of the left femur in the upper one-third of the shaft. In a written statement of his treatment after the fracture, his physician said he had tried first extension and counter-extension, and then a plaster-splint, without being able in either case to retain the fragments in proper apposition. He sent him to the hospital to be treated for *united (?) fracture of the femur*. On admission the patient was a bright, sturdy little fellow, well grown for his age, well nourished, and best family history. He used crutches, and carried the lower extremity in a limp, helpless manner. Toes inverted, pointing toward the dorsum of the right foot. He could, by leaning far over, bring the sole of the foot to the ground, but could not bear any weight on the foot without pain. Examination of the affected limb showed an enormous projection in the upper femoral region, on its external aspect—hard, resisting, not movable, not separable, and no crepitus; acetabular motion perfect, extremity moved as a whole; two and a half inches shortening. Nélaton's line showed the trochanter major slightly higher than normal, and it also projected externally more than normal. It was evident the fracture had united, but in a very bad position.

The parents of the child readily consented to an operation. A short time after his admission this was accordingly undertaken. A curved incision was made over the projection, beginning just below the greater trochanter and extending about three and a half inches downward in the longitudinal axis of the limb. Convexity of incision downward. The incision was carried through the periosteum, which was carefully stripped off, and the bone cleared, when the exact state of the deformity was manifest. The fracture had been about one and a half inch below the trochanter minor; the upper fragment

¹ There were actually 53 major operations, but as 10 of these (*amputations*) were done on cases in absolutely hopeless conditions, merely to render the few hours the patient might possibly live as bearable as possible, they are not counted in the above enumeration. Reckoning these, there would be 53 major operations, with 8 deaths (3 of the hopeless cases had each two limbs torn off, requiring simultaneous amputations), making 15.12 per cent.

¹ This case afterward required amputation of the thigh. The operation (excision) was done several days after the injury, which was crushing of the condyles of the femur and disintegration of the knee-joint; performed because the patient refused amputation. The soft tissues of the lower third of thigh had been so badly injured that he was obliged to have the amputation afterward.

was rotated inward and drawn slightly upward by the iliacus and psoas muscles; the lower fragment was drawn upward and outward by the muscles of the thigh, and they were allowed to unite in this position, the apposition being the lower outer side of the upper and the inner edge of the lower fragment. The union was so firm that it was necessary to use a saw to separate the fragments. A wedge-shaped piece was removed from the knuckle-like projection of bone, firm manual extension was employed to draw the lower fragment into place, which was readily effected. It was with the greatest difficulty that the upper fragment could be reduced, and almost impossible to retain it in place. Good apposition was finally obtained, however, and by means of two double bands of thick silver wire passed through two holes drilled obliquely through the end of either fragment they were retained in apposition. The incision was brought together, large drainage-tube introduced, and Lister dressing applied, after the usual five per cent. ac. carbol. solution syringing. While the patient was still under the anæsthetic, a plaster-of-Paris splint was applied to the whole extremity, with iron brackets over the wound. For a number of days the little patient suffered agonies from spasm of the femoral muscles. This gradually ceased, however, and he made a slow but complete recovery. He was discharged from the hospital with no deformity, one inch shortening, and walking well with assistance of a slightly elevated shoe. I have recently received a letter from his father saying he walks about three miles a day to and from school, has discarded his raised shoe, and knows no difference between his two limbs.

CASE II.—Albert B—, aged thirteen. Phthisical mother. "Hip-joint disease" for five years. Was seen first about one year before the last admission, at which time he entered the hospital, and exsection of head of femur was performed. He improved very much after this, but after three months the upper end of the shaft of the femur had to be exsected. The sinuses still persisting after the operation, he was re-admitted into the hospital October 13, 1882. After a consultation it was decided to amputate at the hip-joint. The boy was quite anæmic, and the urine had already a small amount of albumen in it. The liver and spleen were enlarged; heart and lungs normal. It was particularly desirable in this case to avoid much loss of blood, and knowing that one of the principal bugbears of amputation at the hip-joint is hemorrhage, I was at a loss at first how to prevent it. I finally hit upon an expedient which acted admirably. I have noticed that in applying Esmarch's bandage and retentive band for operations high up on the thigh, the reason why the band did not prevent the blood from flowing back into the limb was that the point of resistance opposite to it, when it should constrict, was a resilient one, and the pull of the band was in a measure counteracted by the elasticity of the tissues of the opposite side. So I reasoned if a firm non-resilient substance be interposed between the band and the opposite side, the whole force of the elastic constriction will be exerted on the limb to be operated upon.

On October 17th the operation was performed. As soon as the patient was anæsthetized I applied a *long Lister splint to the sound limb and side*, put on Esmarch's bandage as usual, the retentive band being applied tightly in a figure of 8 around the groin, just below the anterior superior spine of ilium, over the opposite side, and so return; in short, just as ordinarily done for high operations. I then had the patient drawn down until his buttocks were on the edge of the foot of the table, laid the end of the splint attached to the good limb and side on a high stool, and the patient was firmly and evenly supported, *while not a drop of arterial blood was lost during the operation.* The flaps were formed after the Guthrie manner. Though it was necessary to cut almost under the retentive band, it held on firmly, and did its work faithfully to the last. Besides the removal

of the entire limb, the whole acetabular rim and part of the ramus of the pubis had to be removed. So tedious was this part of the operation that the patient's strength began to flag, and I was obliged to stop the operation before all the dead bone was removed from the pelvis. The lower and inner parts of the flaps were nicely apposed, a large-sized drainage-tube introduced, and, except a space left open on the external aspect, flaps brought together throughout whole extent.

Boy's highest temperature was on the fifth day, and was only 101° F., produced, perhaps, by eating too much solid food. Notwithstanding a large amount of cicatricial tissue, the flaps united rapidly and well; in two weeks, except where the drainage-tube had been, and two or three openings of old sinuses, the wound was healed. He was out of bed in two weeks. Three days later he was walking about the wards. His general condition was much improved at once. Except two or three sinuses, through which the dead bone left near the acetabulum is making its way in bits to the outer world, he has a well-healed stump, and feels perfectly well.

Progress of Medical Science.

A METHOD OF HASTENING THE ANÆSTHETIC ACTION OF THE ETHER SPRAY.—The ether spray is employed frequently at the Hôpital St. Louis in Paris for the production of local anæsthesia. A little procedure, first indicated by Dr. Letamendi, of Barcelona, but not hitherto utilized in practice, is employed by Dr. Vidal to shorten the duration of the process of congelation. It consists in making a slight prick with a needle at the point upon which the spray is directed, at the moment when the skin assumes a purplish hue, and when the ether commencing to solidify assumes an oily consistency. The little puncture made at this time excites a reflex constrictive action of the vaso-motor nerves, the blood is driven from the part, and the skin becomes white. Another method of hastening the process consists in placing little wads of lint about the part, thus increasing the surface of evaporation.—*Revue Médicale*, June 30, 1883.

TUBERCULOSIS FROM CONTAGION.—Dr. J. Lindmann relates, in the *Deutsche Medicinische Wochenschrift* of July 25, 1883, two cases of tubercular ulceration following circumcision. In the first case, in which there was a family history of phthisis, the ulceration healed only after a long time, and was followed by caseous adenitis. Then Pott's disease of the spine was developed, accompanied with symptoms of myelitis, and finally the child died from acute pulmonary phthisis. In the second case, there was no hereditary history of disease. This child, after suffering from enlarged glands and an osteitis of the wrist-joint, finally recovered and remains in good health at the present time. The ulcerations in both cases presented all the characteristics of tubercular ulcers. The children were circumcised according to the orthodox ritual of the Hebrews, in which the circumciser, after cutting off the prepuce and tearing the mucous layer with his nail, takes a swallow of wine and sucks the bleeding parts. The operator in these cases belonged to a family almost all of whose members suffered from phthisis. He himself had been ill for some years, and died from tuberculosis shortly after performing circumcision in these two cases. Dr. Lindmann regards the disease in the related instances as undoubtedly arising by contagion from the phthisical operator.

THE THERAPEUTICAL VALUE OF ARBUTIN.—Although arbutin is no recently discovered substance, it is only of late that it has been proposed to the medical profession as a remedy of value in the treatment of diseases of the genito-urinary organs. This is probably due to the fact that the earliest experiments were made upon the healthy organism, and were not unnaturally negative in their re-

sults. More recent investigations into the action of this glucoside in disease would seem to indicate that we have here a remedy of no inconsiderable importance, and one which may be advantageously substituted for the bulky infusion of *uva ursi*. In a notice of this substance in the *Centralblatt für Klinische Medizin* of July 7, 1883, Dr. H. Menche states that he has found it in many cases to be a most efficient diuretic. It is given for this purpose in doses of about twelve grains per diem, but may be administered in much larger quantities without producing any unpleasant effects. In catarrh of the urethra or bladder, larger doses are advised (forty-five to sixty grains a day). It is excreted in part as hydrochinon, and since injections of a one or two per cent. solution of this latter substance are said by Brieger to be most efficacious in the cure of gonorrhoea, the author suggests that we might in this way avoid the use of the syringe, the topical remedy being contained in the urine. Arbutin exists in the form of fine white, needle-shaped crystals, unchanged by exposure to the air. It is readily soluble in water, has a slightly bitter taste, and no odor. The easiest mode of administration is in the form of powder, which may be dissolved in a tablespoonful of water. It is somewhat expensive, the present price in Germany being in the neighborhood of three dollars per ounce.

THE CHANGES OCCASIONED IN THE ADIPOSE TISSUES BY INFLAMMATION.—From a number of experiments made upon dogs, Dr. Sklifosowsky formulates the following conclusions: 1. In acute inflammation of the subcutaneous adipose tissue the changes in the fat-cells consist in a shrinking and subsequent disappearance of the investing membrane; the fat drops are absorbed and their place supplied by serous cavities. 2. Similar changes also take place in acute inflammation of other parts, as the pericardium, omentum, etc. 3. In chronic inflammatory processes, the retrograde changes of the fat-cells are expressed by hypertrophy and division of the nuclei, and through swelling and subsequent segmentation of the protoplasm. 4. The fat is absorbed through the lymphatic vessels, but whether absorption occurs also through the walls of the blood-vessels is doubtful. 5. In limited inflammation of the subcutaneous connective tissue, no functional disturbance on the part of the heart or lungs was caused by fatty embolism of the blood or lymphatic vessels.—*Centralblatt für Chirurgie*, July 14, 1883.

PNEUMONIA WITHOUT FEVER.—Although in aged or cachectic individuals it is not very uncommon to see a pneumonia run its course without any noteworthy elevation of temperature, such an occurrence under other conditions is rare. Dr. Mazzotti reports a case of this kind in a robust and well-nourished porter, sixty-three years of age. The patient was suddenly seized with sharp pain in the side, cough, and bloody expectoration. Physical examination revealed the presence of a croupous pneumonia involving the left lower lobe. During the entire course of the disease, which terminated favorably, the temperature never exceeded 99.5°, and reached this height but once, being normal the rest of the time. A similar case has been recorded by Korányi.—*Centralbl. für Klin. Medizin.*, July 14, 1883.

PRIMARY TUBERCULAR ARTHRITIS.—Dr. Arnaud concludes an article of some length in the July number of the *Revue de Chirurgie*, as follows: 1. Tuberculosis of the synovial membranes may be primary and independent of any osseous lesion, or secondary to the development of tubercles in the epiphyses. 2. Primary tuberculosis manifests itself in the synovium under the two anatomical forms of ordinary gray granulation and of elementary microscopic tubercle. The latter always accompanies the granular form, but may exist independently of any tubercular lesion visible to the naked eye. 3. Synovial tuberculosis has been chiefly studied in fungoid growths, but it can be detected also where no fungoid changes are present, as in

fibulous tracts, or wherever the neoplasm may be developed by inoculation. 4. The tuberculous nature of a chronic arthritis may easily escape detection unless the naked eye examination be controlled by the aid of the microscope. It would be well always to make a thorough anatomical and histological examination in every case of arthritis, in order to determine the comparative frequency of the tubercular affection. 5. Finally, the author expresses his conviction that a certain number of cases of white swelling and chronic arthritis, fungoid or otherwise, hitherto attributed to scrofula, rheumatism, or unknown causes, will be found upon more careful examination to be tuberculous in their nature.

TREPHINING FOR THE RELIEF OF TRAUMATIC EPILEPSY.—The following case was related to the Surgical Society of Paris by M. Demons, of Bordeaux (*Revue de Chirurgie*, July 10, 1883). A man had fallen two years before, striking his head. He was unconscious for three days, there was an ecchymosis of the scalp, he stated, on the right side, and a paralysis of the left arm and right leg was present for some four or five months. From that time until shortly before coming under observation, he was perfectly well, except for occasional headaches. He was then suddenly seized with repeated attacks of epilepsy, recurring every fifteen minutes, with left facial paralysis, and subsequently with hemiplegia of the same side. The epileptic attacks becoming more frequent and of greater violence, and the intellect becoming clouded, M. Demons decided to trephine. After some hesitation regarding the seat of injury, the trephine was applied to the right side over the fissure of Rolando. As the operation proceeded a crack was seen in the skull, and in the arachnoid was found a little cyst the size of a pea. This was removed, and the surface of the brain was scraped where it seemed to have undergone some alterations. A Lister dressing was applied, and the wound healed readily. The epilepsy and hemiplegia disappeared at once, and had not returned at the time of the report, a month after the operation.

ABSCCESS OF THE POSTERIOR SPINAL REGION IN THE NEW-BORN.—Dr. Guéniot relates two cases of abscess in the vertebral region (one in the neck and one in the back) in children of two and four weeks of age respectively (*Centralblatt für Chirurgie*, July 21, 1883). A diagnosis was made by himself and several other surgeons of spina bifida. The location of the abscess exactly in the median line, its slight change in size upon crying, and the absence of redness or oedema of the skin gave occasion to the error. The mistake was discovered only after an exploratory puncture. The author states in this connection that abscesses may form in young children in any situation. The slight increase of volume in crying is owing to a fulness of the veins caused thereby. The absence of the ordinary oedematous swelling of the skin covering deep abscesses is not uncommon in infants. This fact he explains by the late development of the superficial venous plexus.

TREATMENT OF MALIGNANT PUSTULE BY INJECTIONS OF IODINE.—Dr. Richet relates two cases of malignant pustule treated by injections of tincture of iodine. One died in forty-eight hours, while the other recovered after eight injections of the tincture diluted with two parts of water. In both cases inoculations of animals with pus from the pustules were followed by fatal results. Inoculations with the blood of the first patient were also fatal, while the blood of the second caused no infection. The author concludes from these cases that when the infection is general, when the blood contains the specific bacilli, local treatment is useless. But, on the other hand, if injections at the periphery of the pustule are made before the disease has spread from its point of origin, a cure may be obtained.—*Centralblatt für Chirurgie*, July 21, 1883.

SURGICAL TREATMENT OF DUPUYTREN'S CONTRACTION.—In a brochure on Dupuytren's contraction of the palmar fascia and its treatment, Dr. Chevrot describes a method pursued by Busch in the correction of this deformity. A triangular tongue of skin is dissected up from the palm, the base of the triangle resting in the crease which separates the contracted finger from the hollow of the hand, and the apex terminating at the point of greatest prominence when the finger is forcibly extended. The base of the triangle is left attached while the rest of the flap is dissected up, as much of the connective tissue as possible being raised with the skin. All the contracted bands of the aponeurosis are divided, until complete extension of the finger is obtained. The flap of skin retracts, leaving a triangular space in the palm uncovered. The edges are approximated as far as possible, and a compress applied. A retentive splint should be applied and maintained until the cure is completed. If this method is pursued the danger of wounding the sheaths of the tendons is reduced to a minimum.—*Bulletin Général de Thérapeutique*, July 15, 1883.

THE PERMANENT BATH IN THE TREATMENT OF SURGICAL DISEASES.—In cases after operation in which the ordinary antiseptic dressings cannot be conveniently applied, owing to the location or other conditions of the wound, Dr. Sonnenburg advises a return to the permanent bath. He has met with considerable success by this treatment after operations upon the urethra, rectum, or uterus, or in lithotomy. In the after-treatment of amputations or resections he has found it also useful. The addition of antiseptic substances to the water of the bath, he considers to be unnecessary.—*Centralblatt für Gynäkologie*, July 21, 1883.

ETHER IN THE TREATMENT OF SORE THROAT.—Professor Contalo employs an ether spray in the treatment of pharyngitis. The applications are made several times a day, according to the gravity of the case. Under their influence, it is claimed, the temperature falls, the vessels contract, and the local condition is speedily improved. In two cases a fibrinous exudation was detached and not reproduced. Ether, according to the author, deserves a trial in pharyngeal diphtheria, not only as an antiseptic agent, but also because the pain is thereby greatly diminished, and the taking of nourishment facilitated. Two cases of pseudo-membranous pharyngitis were successfully treated by this method. He insists especially upon the rapid lowering of temperature following the applications of ether spray.—*Journal de Médecine de Paris*, June 16, 1883.

ADENOID GROWTHS IN THE PHARYNX.—The following are the conclusions arrived at by Dr. Pesson in a thesis presented to the Faculté de Médecine of Paris (*Journal de Médecine de Paris*, June 16, 1883). 1. In the upper part of the pharynx, at the junction of the vault and the posterior wall, and between the orifices of the Eustachian tubes, there is an agglomeration of closed follicles which constitute (adopting the expression of Kölliker and Luschka) a true tonsil. 2. This gland is liable to hypertrophy like the tonsils, and then presents the appearance of a cluster of vegetations. These vegetations, already described by a number of writers, are seen usually during the first twenty years of life. Like the lymphatic tissue in general, their natural tendency is to atrophy. 3. These adenoid growths give rise to various troubles of respiration, phonation, and hearing. Children who suffer from their presence, breathe through the mouth and acquire thereby a stupid expression; they complain of frequent headaches, snore during sleep, and are sometimes awakened in the night by asthmatic attacks. The tone of the voice is muffled and faint, and the articulation of nasal words (in French) is difficult. Hearing is often impaired through middle ear disease. These troubles, which often discourage the physician by their obstinacy, disappear spontaneously upon the removal of

the third tonsil. At the same time the deformity of the thorax, described by Lambon and Robert, and attributed by them to hypertrophy of the tonsils, is observed. A careful study of the facts leads to the belief that this symptom is really due to the adenoid vegetations in the pharynx. 4. These growths often determine a chronic catarrh in this region, which is too often referred to a diathesis, but which, like all the other symptoms, can only be cured by treatment directed to the vegetations. 5. Observation leads also to the opinion that deaf-mutism depends in certain cases upon the presence of these adenoid vegetations. Consequently, an opportune diagnosis may lead to the prevention or even cure of deaf-mutism from such cause. 6. Hypertrophy of the third tonsil may be diagnosed by posterior rhinoscopy or by digital examination. 7. The treatment of these vegetations and of the symptoms dependent upon them consists essentially in the extirpation of the enlarged gland.

MYXŒDEMA AND BERIBERI.—Dr. Basil Férís regards beriberi and myxœdema as identical, each being characterized by a more or less general anasarca, together with disturbed function of the nervous system. The exciting causes are the same in each disease, namely, humidity and rapid changes of temperature. He proposes as a common designation the term neuro-vascular hydroparesis, or more simply hydroparesis.—*Revue Médicale*, July 21, 1883.

TREATMENT OF SUPPURATIVE PHLEBITIS.—Dr. Demons related the following case to the Bordeaux Medical Society, as showing the curability of suppurative phlebitis if energetically treated (*Revue Médicale*, July 21, 1883). A man cut the veins of his neck with a razor. A suppurative phlebitis followed, and symptoms of pyæmia declared themselves. In the presence of such an otherwise hopeless condition, Dr. Demons determined to slit up the veins, which he found full of pus. He scraped them and cauterized the lining membrane with a ten per cent. solution of chloride of zinc. An antiseptic dressing was then applied, and the patient recovered. Since then the author has learned that veterinary surgeons sometimes excise the jugular vein in similar conditions, and he thinks that such an operation might be preferable to the one performed by him in the case reported.

EPISTAXIS ARRESTED BY HOT-WATER DOUCHE.—Dr. J. H. Stuart, of Minneapolis, sends us a report of the following case: "On July 14th last I was called to see a laboring man, about thirty years of age, who had been bleeding at the nose for nearly twenty-four hours. The epistaxis seemed to have been caused by sitting in a draught of air, in the evening, with a portion of his clothing left off, which produced a stuffiness in the nares. Various remedies had been used, but with no relief, and the loss of blood was sufficient to produce a very perceptible impression on his pulse, accompanied by a feeling of faintness. Having determined to try the value of hot water I took with me apparatus for douching the nose, and having procured a pitcher of warm water (not as hot as I desired) I passed it in a continuous stream through the nares. The hemorrhage seemed to be checked for a while at least, but soon the bleeding side was filled by a clot, and again it showed itself both posteriorly and anteriorly. I procured another pitcher of water as hot as I thought could be borne and douched the nose as before. I continued the douche until the water escaping was almost free from any stain of blood—using perhaps a gallon. After this there was no bleeding, not even the formation of a clot in the nostril; but the patient, breathing freely through both sides, went to bed about 10 P.M. and slept till morning without any return of hemorrhage whatever. It is true I endeavored after each douching to throw a solution of tannin into the posterior nares, but I attributed little or no benefit to this procedure."

THE MEDICAL RECORD:

THE PATHOLOGY AND TREATMENT OF METRIA, OR SO-CALLED PUERPERAL FEVER.

METRIA, the gynecological, and, in this instance, proper name for the so-called puerperal fever, has recently been the subject of three very instructive, as well as interesting papers, read before the British Medical Association.

There is scarcely a question but that the term metria should be substituted for "puerperal fever." Dr. Thorburn justly remarks that "puerperal fever" does not cover the ground, for it is almost impossible to include epidemic puerperal fever under the same classification as the more sporadic forms; and again, the use of the term precludes the inclusion of cases of metria caused by zymotic diseases. Regarding this he says, as is well known, that the poisons of scarlatina, erysipelas, or typhoid fever may sometimes cause in puerpera symptoms scarcely distinguishable from those of puerperal fever; yet Mathews Duncan and his followers, who wish to make puerperal fever a disease *sui generis*, do not include zymosis with septicæmia or in their list of etiological factors. Again, a puerpera who has scarlatina which can be distinctly diagnosed, has scarlatina; but a woman who has sudden rigors, intense tympanites, high temperature, and rapid death, with subsequent clear proof of scarlatinal infection—with perhaps the occurrence of the typical rash in the hour of death—has puerperal fever or metria caused by scarlatina. Zymotic diseases may occur in puerperal women without causing puerperal symptoms, and should be then designated by their proper names; but when, with that zymotic affection, puerperal symptoms manifest themselves, shall we confine our nomenclature to one or to a combination of the two? Clearly the latter, and metria is then the proper designation.

Precisely the same causes are at work whether scarlatina or erysipelas be sporadic or epidemic, and may in the latter case produce a severe and fatal epidemic analogous to what occasionally occurs in hospital, more rarely in private, obstetric practice. Arguing from this point of view, Dr. Thorburn thinks that there would be no difficulty in conceiving how a tolerably definite train of symptoms ensuing from the action of septic or zymotic germs in the hyperfibrinated blood of a puerperal woman may, in some cases, take on a uniform character and epidemic virulence. Clearly another name than puerperal fever is needed, and if we need another what is better than metria?

As regards the pathology of metria, the two points ar

stated by Dr. Lombe Atthill as admitted by all. First, under certain circumstances puerperal women are liable to be inoculated with septic material conveyed to and deposited in the vagina by the hands of attendants and other agencies, when proper precautions against this infection have not been adopted; the disease produced by this inoculation being frequently a source of one of the forms of metria; and second, puerperal women may be the victims of auto-inoculation, the poisonous material originating within their own bodies from the decomposition of blood-clots and placental remains after parturition. The disease thus produced Dr. Mathews Duncan prefers to call "sapraemia"—or a result of the absorption of putrid material—distinguishing it from "septicæmia, a disease produced by organisms which, when conveyed to the blood, multiply indefinitely in it;" Dr. Duncan holding that organisms resulting from putrefaction do not survive, far less grow, in the blood. The merits of the last proposition we will not now discuss; indeed, we rather doubt if it has any.

In addition to these two forms of metria Dr. Atthill asks if there are not two other forms which it may not be possible to guard against. First, a form of auto-infection occurring under special conditions and not preventable by antiseptic precautions, but happily preventable in many cases by other therapeutic measures. This form occurs in cases of continued uterine relaxation, thus leading to the second of the varieties already mentioned. The uterus does not properly contract, blood-clots are retained in its cavity which decompose and thus produce the disease. This condition of the uterus also favors the formation of other clots than those directly resulting from parturition, and the sinuses being kept open, favor the absorption of septic material. Though antiseptic measures are powerless here, the enemy can be combated by the administration of ergot, continued after labor until the desired effect is produced. As is well known, this condition of relaxation occurs most frequently after rapid deliveries. A consideration of these, we may say, facts, has led Dr. Atthill to believe that a relaxed condition of the uterus—doubtless caused in a great measure by the great mental distress—is one of the causes of the frequent occurrence of metria in unmarried women. Clearly in these cases the prime cause, viz., relaxation of the uterus must be combated by oxytocics. The mortality among this class of patients is very great, and in the absence of hitherto successful means of staying it, it is advisable that this remedy have a thorough trial. It is important to remember, however, that many cases of uterine relaxation will yield to persistent kneading, one hand being placed on the abdomen, and the other introduced into the uterus.

A late paper by von Swiecicki (*Centralbl. f. Gynäk.*, No. 16, 1883), in which he expresses the opinion that persons engaged in obstetric practice should not perform *post-mortem* examinations, or dissect, or if they do should quarantine themselves from the lying-in chamber for a certain length of time, has been followed by a free expression of opinion. Löhlein takes exception to v. Swiecicki's arguments, believing that proper antiseptic measures are all that is necessary, and Fritsch, in commenting upon Löhlein's paper, practically agrees with him (*Centralbl. f. Gynäk.*, No. 23, 1883). It would

seem, however, that antiseptic precautions alone are not a sufficient safeguard. Löhlein and Fritsch have had, it is true, exceptional good fortune, but recent experiments have shown that micro-organisms are not so easily destroyed by antiseptic agents, and we doubt much if simply washing the hands in antiseptic solutions will obviate the risks of inoculation after handling septic material; and the adoption of Dr. Atthill's rules is by far the safest method. Students attending the patients of the Rotunda Hospital in Dublin, are not allowed to dissect or make post-mortem examinations, or attend a hospital containing patients suffering from infectious diseases; and before examining any patients they are required to wash their hands in a solution of carbolic acid. During the first six and a half years of his mastership in the Rotunda, these precautions sufficed to prevent anything like an epidemic of puerperal septicaemia.

The treatment of puerperal sepsis is but little, if any, more satisfactory than its pathology. When several cases, coming with shorter intervals, occur in a hospital, there is but one method to be pursued. The patients must be removed, the wards disinfected, the floors and walls washed with strong disinfecting solutions, and everything else thoroughly disinfected. As to the choice of a disinfecting material, it would seem that corrosive sublimate is the most certain in its effects. In private practice prophylactic cleanliness, thorough emptying of the uterus after delivery, and the insurance of uterine contraction, are the best and only safeguards so far as the woman is concerned. It is scarcely necessary to reiterate the cautions as to the cleanliness of instruments and the hands of the accoucheur. When, however, by any mishap, the puerperal woman is seized with the disease, our main reliance must be placed in quinine, intra-uterine injections, opium, and stimulants. At present, cases of puerperal sepsis are extremely liable to take on a remittent form, and quinine must be given in full doses. In America and other countries where the malarial element is predominant, the dose of three to four grains every three or four hours, recommended by Mr. Thomas More Madden, is scarcely less than child's play. It is important to remember that a given amount of any drug is not a dose unless it has the required effect. It may also be stated quite positively that the day for depletion in these cases has passed. As a rule, they assume an asthenic type and need stimulation. Intra-uterine injections are of the utmost importance, but caution is required in their use, and to employ a syringe which is not perfectly clean is worse than useless. Lastly, the bowels should not be neglected, and it is important that they should act, and thoroughly, before the patient is fully under the influence of the opium, in case that drug be employed; for in these cases it is extremely difficult to re-establish peristaltic action after it has once been paralyzed.

THE PROPER CARE OF THE EYES OF THE COMING GENERATION.

IN connection with the late address of Mr. Charles Francis Adams on "A College Fetish," and our recent editorial, "Greek or German—Which?" it may not be entirely foreign to make a few remarks on the subject of the German Alphabet from a hygienic point of view. The systematic examination of the eyes of school-children

might lead one to suppose that the youthful Teutonic eye is presbyopic, hypermetropic, ametropic—anything except normal. Dürr found the average myopia among the scholars of a Hanoverian school to be 31.7 per cent. Reich found an average of 33 per cent. in another school. Nor is the solution at all difficult to one who has turned from an English to a German book printed in the abominable text of the latter language. German authors are inclined to attribute this to the position during writing, bad light, etc. These may be factors, but they do not seem to have thought of their outrageous letters, and still more outrageous script. Every one acknowledges the importance of the German language, especially in scientific studies. But why should American children, and adults, for that matter, be compelled to gain their first knowledge of that beautiful and expressive language by poring over its crooked, "sich ähnlichen" letters? The grammars, dictionaries, and general literature are printed in this text, and nothing else, so far as we are concerned. All, or almost all of the German books used for instruction in this country are printed here, and is there any reason why they should not present a respectable appearance in English type? Surely there is every reason that they should. The myopic eye turns from the neat and inviting page of the *Berliner Klinische Wochenschrift*—or any other German journal—to the bewildering fog of the dictionary printed in America, and figuratively groans. Here is room for a needed reform. The proper care of the eyes of the coming generation is of vital moment. School boards and teachers have it in their power to banish this evil from our schools. Let them do it, and our bookmakers will take the hint.

ENGLAND AND THE CHOLERA.

THE English are beginning to show signs of displeasure at the comments of the Continental press upon the cholera in Egypt and the responsibility of Great Britain for its outbreak in that country. Lord Granville has recently addressed a communication on this subject to the Minister of Foreign Affairs of France. In this note the principal accusations of the foreign press against England are summed up as follows: 1. The origin and mode of propagation of cholera are well known and well understood. 2. Quarantine is the recognized and successful means of preventing the spread of the epidemic. 3. Cholera is always brought by ships coming from India. 4. Her Majesty's government has profited by its situation in Egypt to compel the Egyptian government to relax the only precautions known to prevent the spread of the disease, in order that British commerce may not be impeded. 5. Her Majesty's government has consequently deliberately introduced the cholera into Egypt. To all this Lord Granville answers by a general denial: The origin and mode of propagation of cholera is as yet undetermined; quarantine is valueless as a preventive measure; cholera is not brought to Europe by vessels from India; and lastly, although not believing in quarantine, England has done nothing to interfere with the regulations of the Egyptian government in this regard. The British Foreign Office request that its communication be given publicity in order that its misapprehensions regarding England's conduct in this matter may be re-

moved from the mind of Europe. We doubt, however, whether Europe will accept the views of the British ministry on the nature of cholera. But the symptoms of irritation are not confined to official quarters. The *Medical Press and Circular* grows angry at its brother of the *Wiener Medizinische Zeitung* for speaking in a disrespectful manner of England's remissness. It quotes at some length from the offending article in question, and concludes in a somewhat excited strain, as follows:

"The article contains more, much more, of this hysterical nonsense. The writer, if he ever had any wits, has plainly been *erschreckt* out of them by the *schwarzem Gast vom Ganges und Bramaputra*. It is not necessary to make further comments on such a ridiculous production, in which imagination and spleen have performed the duties that ought to have devolved upon reason, and which would have been unworthy of notice on our part had it not received an official stamp as an editorial."

In spite of dignified official utterances and somewhat less dignified journalistic protests, the world will probably persist in the belief that England has not done her whole duty in respect to the cholera in Egypt.

THE CURE OF CHOLERA BY COLLODION.

DURING the recent epidemic of typhoid fever in Paris, the number of remedies proposed for the cure of this disease was legion. Volumes were written to prove that this or that method was certainly infallible, and that all that was needed to stamp out the epidemic was a general conformity by the profession to the views of the writer. In spite of these valuable discoveries, however, the epidemic went on. The time is now ripe for the publication of sure cures for cholera, and we shall soon be so abundantly provided with never-failing remedies that the fame of the "*Sun* mixture" will pale by comparison. Among the first to enter the field is Dr. Arsène Drouet in *Le Courrier Médical* of July 28, 1883. The method is very simple, and consists merely in the application of collodion to the abdomen. He says that nature, when she essays to cure cholera, does so by determining a perspiratory crisis, and collodion acts in a similar fashion. After its application it irritates, by reason of its constructive action, the nerves of sensibility whose terminal filaments lie in the skin of the abdomen. Thence a reflex inhibitory action is exerted in the motor, vaso-motor, and secretory nerves, and there follows an immediate arrest of vomiting and alvine discharges. Then, little by little the blood returns to the subcutaneous capillaries of the abdomen, the surface becomes warm, and finally a profuse perspiration breaks out, carrying with it the *materies morbi*. As a beverage, the patient is allowed cold water or seltzer. By this method Dr. Drouet claims to have cured two hundred cases of cholérine and thirty cases of true cholera. The favorable reaction commences within ten minutes and proceeds with a rapidity so extraordinary that it must be seen to be believed. Cholérine is always cured by a single application of collodion within five hours. Severe cases of undoubted cholera require two or three applications, at intervals of one hour, and are only cured in from six to seven and a half hours. The first coating is made with ordinary contractile collodion. A piece of coarse

cheese cloth or mosquito-netting is stretched tightly across the abdomen, and over this the application is made. When the contraction becomes painful the film of collodion is removed by pulling off the cloth, and then a second application is made of flexible collodion which has still contractility enough to produce the desired effect. This method is not new, and has singularly enough been discovered by four observers in different countries and at different times. In conclusion, the author suggests that the inhabitants of countries ravaged by cholera be instructed to carry about little phials containing collodion, and to paint their own abdomens upon the earliest symptoms of the dread disease declaring themselves. Further, if this treatment be practised on board ship, every case of cholera could be cured at once, and there would be no more need of quarantine.

We can only express our surprise that Dr. Drouet did not hasten to Egypt upon the earliest tidings of the outbreak of cholera in that unhappy land, and there demonstrate the value of his method. Aside from the sweet consciousness of having saved the lives of untold thousands of Egyptians, and of having in all probability averted the scourge from Europe and America, he would have achieved a fame beside which that of all others of the world's heroes would have paled. A grateful world would have loaded him with riches and honors, and his name would have been cherished by all coming generations to the end of time. Perhaps, however, he was unwilling to rob Pasteur of the glory of discovering the microbe of cholera.

HÆMATEMESIS FROM WASHING OUT THE STOMACH.

IN 1881 Bouici pointed out the advantages of washing out the stomach in cases of simple ulcer, reporting at the time a patient, very cachectic, with constant rejection of food, both liquid and solid, who had had several hæmatemeses, and who rapidly gained flesh and strength and digestive ability after the commencement of the washings. Bucquoy had already reported, in 1880, a case of simple ulcer, in which washing out the stomach arrested the vomiting. Küssmaul had also reported similar good results, and, as is well known, Débone has treated a large number of cases in this manner.

In spite of these favorable cases, in which no mention is made of hæmatemesis, Germain Sée, in his work on dyspepsia, looks upon this procedure unfavorably, as he believes that there is a risk of destroying a vascular wall and thereby producing hemorrhage, or of re-opening an imperfectly formed cicatrix, and provoking a new hemorrhage.

Cornillon has recently reported a case which seems to bear out these views of Sée (*Le Progrès Méd.*, No. 17, 1883). An alcoholic person, who for ten years had suffered more or less from epigastric pain and vomiting, consulted Cornillon about two years after vomiting a quantity of clotted blood. Cornillon introduced about a quart and a half of water into his stomach, and found, on siphoning, that it contained a substance similar to black coffee. On repeating the washing, there was less of the black substance, but when water was introduced a third time, it returned distinctly reddened, and containing a number of clots. When the washing was repeated two days later, there was quite marked hæma-

temesis. Cornillon attributes the hemorrhage to the quantity of water, and the force with which it was introduced, and he doubts the propriety of this measure in cases of recent ulcer, for fear of dislodging a clot and thus provoking hemorrhage.

READING OF MEDICAL BOOKS IN COURT.

REFERENCE was made in these columns a short time since to the rule in vogue in the courts of a large number of the States, forbidding the reading of medical books to the jury, in criminal cases.

This rule had an illustration in a Michigan court a short time since, where a verdict was reversed because the counsel on one side had succeeded in a device to get the book before the jury. The facts were these: On the cross examination of a physician who was testifying for the defence, he was asked if he was acquainted with a certain book. He replied that he had heard of it, but had not read it. He was then asked whether it was considered good authority, and he said it was. He was then requested to read a certain paragraph during the recess of the court. When the court convened again he was recalled, and counsel reading from the book the paragraph to which his attention had been called, asked him whether there was a case reported of taking sulphate of zinc, followed by vomiting, purging, and death? As this was what the paragraph stated, the evident purpose of the question was to put the passage from the book in this indirect manner before the jury instead of reading from it directly. The question having been allowed by the judge and answered by the witness, the Appellate Court held the error to be sufficient for a reversal.

THE DEGENERACY OF THE FRENCH INDIVIDUALLY AND AS A NATION, AND WHAT TOBACCO IS ACCOUNTABLE FOR.

A SUCCESSOR of the late lamented Trask has appeared across the water in the person of Dr. Decroix, who raises his warning voice against tobacco, and threatens his fellow-mortals with ruin—physical, moral, and mental—if they do not rise in their might and stamp out the weed. In a communication recently presented to the Academy of Medicine of Paris, he takes a most gloomy view of the future of the French race, and incidentally of the rest of mankind. He says that the death-rate in France greatly exceeds the birth-rate, and that the population of the country is steadily decreasing. It is becoming difficult to find recruits for the army who are physically fit for military service, and the average stature of the individual is constantly becoming lower. Morals are becoming lax, and crime is growing more prevalent. Physical beauty is rare, and mental alienation and idiocy are increasing at such a rate that the asylums are unable to contain all the unfortunate victims. The cause of all this moral and physical decay he finds in the use of alcohol and tobacco. The picture he draws of the baneful influence of these poisons, the latter especially, upon the social body, is one fearful to contemplate. This it is that effaces the lines of beauty in the countenance and in the form; this it is that degrades the intellect and corrupts the moral nature. Here is to be found the active cause of sterility, or if by chance a baby is born, this is the demon that robs it of its mother's milk, the fiend that chokes with its damnable

nicotine the lacteal springs that lie deep down within the maternal breast. It kills one-half of all who see the light of day before their little lives have spanned a semicircle of the year.

Spain was once the mistress of the sea, the proud ruler among nations, the queen of poetry and song, the home of chivalry and valor, rich, proud, beautiful, wise, virtuous, and renowned. It sent its fleets to the far West to explore the new land, and to bring back its treasures of gold and silver and precious stones. The stately ships returned, laden not only with all the riches of Eldorado, but also, alas! with the "panacea of the Indies," the noxious weed—tobacco. From that period dates the decadence of that once glorious nation. The habit of smoking the poison spread with fearful rapidity over the devoted country. It seized upon the king and the peasant, the holy bishop and the humble donado. Lords and ladies all smoked and smoked until the once fair land was enveloped in nicotine-charged mist, and the glory of Spain was but a thing that is gone. And this is the fate in store for luckless France. Tobacco was the cause of the disasters of the Franco-German war, and tobacco will be the occasion of far greater evils still to come.

Undoubtedly, tobacco has much to answer for. Its injurious effects upon growing boys are quite evident, and it is truly a saddening sight to see children hardly six years old pulling away on the cheap and nasty cigarettes which have recently descended upon us like one of the plagues of Egypt. But to claim that Spain's decay resulted from the use of tobacco, and that France will owe its inevitable fall to the same cause is, to say the least, an extravagant assertion. It is a pity that apparently earnest men, advocates of temperance in material things, should so often themselves be intemperate in words. Nothing good or lasting was ever accomplished by falsehood, and nothing good or lasting can result from its twin brothers, exaggeration and distortion of facts.

News of the Week.

PROGRESS OF THE YELLOW FEVER.—During the past week no cases of yellow fever have been reported in the United States outside of the Pensacola Naval Reservation and the Government quarantines. Only five new cases and three deaths at the navy yard have been reported, and the house-to-house inspection of the adjacent villages of Woolsey and Warrington, as well as the inspection at Pensacola, have discovered no hidden cases, so that hopes are entertained that the disease has spent its force and will soon disappear. There is much suffering among the people of the villages (squatters), who are unable to provide themselves with the necessities of life, and many appeals have been made in their behalf for aid out of the Epidemic Fund, but the Department has decided that only those in hospital or under treatment are proper beneficiaries of the fund. Governor Bloxham also states that he is unable to help them, as there is no appropriation for the purpose, and thinks as they are on the Government reservation and quarantined by the Government, that it ought to take care of them.

The report of Acting Assistant-Surgeon Fitzhugh Finney for the past week shows twelve vessels in quarantine

at Ship Island and nineteen cases of yellow fever and five of ague, with three deaths from the former disease. Reports from Sapelo quarantine show no transactions, no infected ship having put in at that station. At Cape Charles quarantine a vigorous inspection is kept up by Surgeon Smith who boards all foreign vessels, whether from infected ports or not.

Sanitary Inspector Burgess telegraphs from Havana the departure of the following named infected vessels for the ports stated: Bark Doce de Juno, for Brunswick, Ga.; Spanish bark Christiana, for New York.

Thirty-two deaths from yellow fever occurred at Havana during the week ending August 24th, and there is still considerable yellow fever in the city, but very little among the shipping. It has been officially reported that the Captain-General recently issued an order forbidding the Consul to issue bills of health and directing the local board (sanitary) only to give them. No attention will be paid to this order by the United States Consul, as no faith can be placed in the sanitary report of the local board, particularly as their "fumigation" of vessels consists in giving to the master a four-ounce vial of mild fumigant for which he is charged ten dollars, and which the master throws overboard!

To form some idea of the sanitary condition of Cuba the following translation of an article which appeared in the *Matanzas Correo de la Tarde (Evening Mail)*, of August 18th, is herewith presented. The first paragraph was difficult to translate, because in the editor's effort to be ironical he forgot his logic—however, it will pass:

"It is often said, and generally believed, that Cuba is not healthy, and yet the facts are that this description cannot be more unjust or untrue, because if there exists in every other town the same noxious elements which are apparent here (Matanzas), and if all could show the same proportion of mortality, a proportion which, without exaggeration, is much below the average,—it deserves the name of being very healthy; and yet it is strange, all things considered, that a single soul lives.

"Picture to yourself a city which is bounded on one side by the marshes of the Yumury, whose deadly miasma is daily swept over it by the breezes which generally blow from that direction, and on the other side by a bay into which a great deal of organic matter is deposited by the currents of the two rivers. Picture to yourself other marshes which exist behind the suburbs of the town. Picture again to yourself a provision market always dirty, and surrounded by a sewer which continually gives forth bad odors. Go on picturing to yourself that in the centre of the town there exist many streets full of cesspools and filthy ditches, and on every two or three corners piles of offal. Picture to yourself, again, that on the banks of one of its rivers, which is the city's chief source of commerce, one sees immense sheets of stagnant water, covered by a greenish scum, and which renders a communication with the above houses almost impossible. Picture, lastly, to yourself that from the milkman at one corner of the street to the fisherman at the other, whose strident yells distract and annoy us—that from the butcher behind his counter, awaiting his victims, to the fruit and vegetable dealers wandering through the streets—that from the most elegant café to the humblest grocery store, they can in spite of all law sell us a 'cat for a hare,' as the vulgar

say—and in face of all this, dispute the statement we have expressed above.

"The vigor with which the question is treated in the capitals of Europe is unknown to us—as our condition is inconceivable to them. They cannot understand that possessing laws, as we do, exacting as their own, we should permit them to become dead letters from the indifference with which they are treated. But for that would they sell us the adulterated milk, which does not kill because, like Mithridates, we are used to poison? Would our streets otherwise be filled with numberless pedlers, free from the danger of molestation, offering us for sound, rotten fish? And others offering as harmless fruit ripened by fire? And still others offering for sale tainted flesh which they bring in their filthy trays? But for this marked indifference would so many vagabond dogs wander through our streets, and so many horses be attacked by suspicious coughs? It is necessary, therefore, that this lamentable state of affairs should be remedied for the good of all and the satisfaction of our own conscience. And would that our humble words, which have no tendency except the common weal, might carry this conviction to certain minds."

Sanitary Inspector Mainegra reports by letter that the sanitary condition of Vera Cruz is much improved, owing to copious rains with thunder and lightning refreshing and purifying the atmosphere. He states that the type of the fever has been very fatal, the mortality even among private cases being about thirty per cent. As there is no reports made by the authorities, he was unable to get at the whole truth, but thinks it would show a still greater mortality. He gives the following figures: Deaths in 1882, 72; in 1883—January, 1; February, 1; March, 7; April, 16; May, 90; June, 261; July, 200; August, up to 16th, 38. He regards all vessels sailing from Vera Cruz infected, and if bound to any Southern port, advises them to put in at Ship Island or Sapelo Sound quarantine station for inspection.

The U. S. Consul at Tampico, in a despatch to the Secretary of State says: "I have the honor to report that the authorities of this port have, since the 1st of this month (August), established a quarantine of eight days against all vessels arriving from Vera Cruz and from other infected ports—that term to be reckoned for vessels arriving from Vera Cruz, from the date of departure therefrom. This port and vicinity enjoy good health to this date, and there is no suspicion of plague, cholera, vomito, or contagious distemper whatever in this district."

The United States Consul at Matanzas, Cuba, in transmitting his weekly consular report of the sanitary condition of that place says: "The sanitary authorities all combine to withhold information from me; however, sufficient cases of yellow fever exist to seriously infect the port and make watchfulness a necessity, and strict quarantine a matter of wisdom. The Captain-General has issued orders forbidding Consuls giving Bills of Health, transferring that duty to local sanitary boards, and I would suggest that if any foreign vessel enters without my Bill of Health, that the penalty prescribed by law be enforced."

In answer to a despatch of inquiry sent the Consul at Saint Thomas, W. I., he states that there has not been a case of yellow fever at that place for the past two years.

There were twenty-nine deaths from yellow fever at Havana last week.

PROGRESS OF CHOLERA.—The department of State has received and transmitted to the Treasury department despatches from the U. S. consul-general at Constantinople, dated July 19–21, in regard to the cholera in Egypt and the sanitary condition of Constantinople. He says that when the cholera was reported in Damietta it created the greatest alarm in Constantinople, and stringent orders were immediately issued to exclude it from the country, as well as to combat its ravages if it succeeded in getting a foothold. All arrivals from Egypt were required to undergo quarantine at the entrance of the bay of Smyrna. The limited accommodations at Beirout and Bouria were enlarged, but the panic-stricken refugees from Alexandria came in such numbers, that the quarters soon became insufficient to accommodate them; and as each day brought fresh arrivals, the sufferings of the people from exposure to the burning sun and the chilly night dews became very great, and threatened to create the very evil it was intended to guard against. The arrivals at Beirout were the greatest sufferers, and the authorities were finally compelled to telegraph to Alexandria to give warning that no more refugees could be received, or would be allowed to land. But while the sanitary administration were employing the best means their resources admitted of to prevent the introduction of cholera, the orders from the palace for the cleansing and disinfection of Constantinople were totally neglected, as was also the case in the provincial towns. The most elementary measures of precaution had not even been commenced, after the cholera existed at Damietta for over a month. The ditch draining into the Golden Horn, which drains about two square miles of land thickly built up and densely populated, receives, through a thousand tributaries, all the sewerage of that large district. It is an open stream of filth, and its noxious gases spread with every breeze to distant quarters. This pestilential ditch still yawns and befouls the atmosphere of Pera, and other quarters facing the Golden Horn. While the authorities are discussing measures to improve the sanitary condition of the city, the streets remain unswept, the sewers choked and overflowing, or open, and indescribable filth and garbage go on increasing in open spaces the accumulation of years. The consul-general says that, as under these circumstances it can scarcely be expected that Constantinople will escape a visitation of cholera, it is his duty to call the attention of our sanitary authorities to the necessity for taking prompt precaution against its importation into the United States. There are several classes of goods that originate in the East, that have been active agents in the introduction of infectious diseases—hides and skins, rags, rugs, and carpets, and woollen, cotton, silken, linen tissues and embroideries, mostly old and worn. It will be no safeguard that these goods reach the United States through European ports, unless there is evidence that the packages have been opened and disinfected before reshipment. Danger is especially to be apprehended from rugs, which come from remote parts of Asia. It is well known that when the plague has prevailed in Constantinople, the bazars where these goods are sold were centres of infection.

Russia has virtually put the whole world in quarantine as regards her southern ports, as an order has been issued that all vessels passing the Dardanelles, under whatever flag, shall be subjected to quarantine on arrival at any of the Black Sea ports.

The consul-general encloses tables giving the number of deaths from cholera in Egypt, to July 15th, as 2,932, of which Damietta had 1,740, and Mansourah 825, and says, considering the density of the population of the delta of Egypt and the habits of the inhabitants, the rates are not extraordinary. The outbreak of the cholera is sufficiently accounted for by the condition of the towns infected. Before the epidemic appeared a cattle plague of extreme virulence had been raging for some time, and such of the infected animals as were not slaughtered for food were allowed to die of the disease, and after being skinned, their carcasses were thrown into the river and canals, whence all the drinking water is drawn. The hides, after drying, were stored in the villages to be sold. In some places carcasses were tied to the banks of the river to attract fish and render their capture easier, and these fish, feeding on putrefied flesh, were sold for food. The water in many of the canals is almost stagnant, and has become putrid from the number of carcasses thrown into them. Everything seems to have been done to create and propagate cholera, and it is quite useless to seek its origin in India, when such abundant causes for its generation exist in every part of the Delta. Since the military cordons have been established around infected places—either through ignorance or from malevolence—they not only do not allow any one to pass out, but they allow nothing to pass in, not even provisions or medicines. Meanwhile the dwellers in these plague-stricken places are without food and medicines, and it is not to be wondered at that they should eat the carcasses of animals that have died of disease, preferring to risk the chance of cholera rather than incur the certainty of death from starvation. The wonder is, not that there is cholera in Egypt, but that the mortality is not much greater than reported.

The consul reports the population of some of the principal towns of Lower Egypt, according to the recent census, as follows: Cairo, 368,108; Alexandria, 208,778; Port Said, 16,560; Suez, 10,913; Tintah, 33,725; Damietta (where the cholera made its first appearance), 34,068; Rosetta, 16,671; Mansourah (second place attacked), 26,784; Zagazig, 19,046; the whole of Egypt, 6,798,200.

Sanitary Inspector Hill, stationed at London, England, in his abstract of "Bills of Health," states that the British steamer Newcastle City "left port in a dirty state, with 335 tons of rags and paper-stock (200 tons British, 35 Parisian, 80 Russian, and 20 Dutch) for Boston; and that the British steamer Canada carried 120 tons of rags obtained from Northern Prussia." He also states that deaths in London from choleraic diarrhoea number six to eight each week.

At a meeting of the Board of Health, held at Gibraltar on August 10th, it was decided that all arrivals from Syria and from the Ottoman ports be subjected to a quarantine of twenty-one days.

PROCLAMATION.—By His Excellency Sir John Miller Adye, Royal Artillery, Knight Grand Cross of the Most

Honorable Order of the Bath, Knight Commander of the Legion of Honor, and of the First Class of the Military Order of the Medjidie, Lieutenant-General of Her Majesty's Forces, Governor, Vice-Admiral, and Commander-in-Chief of the City and Garrison of Gibraltar, etc., etc., etc.:

Whereas in and by a certain Order, bearing date at the Court at St. James's on July 13, 1830, and made by His late Majesty, by and with the advice of His Privy Council, to regulate and provide for the performance of Quarantine at the Garrison and Territory of Gibraltar, it is among other things ordered that the Order or Orders from time to time made by the Board of Health of Gibraltar, in pursuance of the said Order of His late Majesty, for carrying into effect the Regulations and Provisions thereof, shall be duly published at Gibraltar by Proclamation.

And whereas the said Board of Health having made the Order hereinafter following, the same is hereby published and proclaimed in pursuance of the said Order of His late Majesty in manner following, viz: That all arrivals from Syria and Ottoman Ports be subjected to a quarantine of twenty-one days.

Given at Gibraltar, August 10, 1883.

By Command, GIFFORD, *Colonial Secretary*.

Official reports up to August 31st, show that there have been 27,318 deaths from cholera in Egypt since the outbreak, this includes 140 among the British troops stationed there.

Official reports from Shanghai, of July 23d, received by the State Department, announce the fact that "the cholera had assumed an epidemic form at the Port of Swatow, but while many deaths had occurred in consequence, they were confined entirely to the shipping and native population. Hong Kong has declared Swatow an infected port, and strictly enforced quarantine regulations against vessels arriving from there." The Consul-General called a meeting of the Consular body to take action for the protection of Shanghai by the enforcement of quarantine regulations, and he was requested to communicate with the Chinese officials, asking their co-operation in the enforcement of the regulations of 1874. Nearly all the cases occurring at Shanghai have also been among the shipping and natives—those dying among the foreigners were mostly sailors.

DR. HENRY MAUDSLEY is visiting this country. He stays but a short time and is travelling very quietly, being desirous of obtaining rest and health.

SANITARY REFORMS IN TORONTO.—The people of Toronto are becoming awakened to the real value of preventive medicine. Dr. Oldright, Chairman of the Provincial Board of Health for Ontario, and Dr. Canniff, health officer for Toronto, have been busy lately looking into matters of public health and reporting upon unhealthy localities and nuisances. Policemen have been detailed in pairs to make a thorough inspection of Toronto. They are authorized to go into houses, stables, yards, cellars, factories, schools, etc., and are provided with blanks to make reports on in the event of any unhealthy condition being found. Although Toronto has taken the lead in this matter, other cities are moving in the same direction. Much good must follow so systematic a

course of investigation. The Committee on Public Health of the Ontario Medical Association urge strongly that hygiene be taught in all the public schools in lieu of less important subjects.

CONVALESCENT HOMES IN CANADA.—Considerable attention is being directed to convalescent homes, both in connection with the general hospital and for sick children. In the case of the latter a neat summer resort has been erected on the island about a mile from Toronto. Here the little invalids are removed from all noise and disturbance and get the benefit of the cool Lake Ontario breeze. More of such places are required throughout the country in healthy, open localities, instead of large, dreary hospitals in busy, crowded cities. There is ample room for them, and abundance of means to sustain them. It requires but the stimulus to be given in this direction and we shall soon have many of these suitably located convalescent homes.

AN EPIDEMIC OF DYSENTERY.—The *Mississippi Valley Medical Monthly* states that an epidemic of dysentery is now prevailing at Byhalia, Miss., about twenty-five miles from Memphis. Sixty or seventy deaths have recently occurred in that vicinity, and considerable alarm prevails. It is rumored that some neighboring towns have instituted quarantine for protection.

MEETING OF GERMAN NATURALISTS.—The fifty-sixth annual meeting of the Society of German Naturalists and Physicians will be held at Freiburg, on September 18th, 19th, 20th, and 21st.

NEW HOSPITALS IN PARIS.—The Municipal Council of Paris has recently voted a credit of \$600,000 for increasing the hospital accommodations of that city. The sum of \$400,000 is to be devoted to repairs and additions to already existing hospitals, while the balance of \$200,000 will go toward the erection of a hospital for the treatment of chronic diseases, a small-pox hospital, and a children's asylum for incurables. The entire cost of these three new hospitals, when completed, will aggregate about \$2,250,000.

THE EIGHTH ANNUAL MEETING OF THE AMERICAN GYNECOLOGICAL SOCIETY will be held in Philadelphia, at the Hall of the College of Physicians, on Tuesday, Wednesday, and Thursday, September 18th, 19th, and 20th. Papers are expected to be read as follows: "Superinvolution of the Uterus," by Dr. Joseph Taber Johnson, of Washington; "The Importance of Cleanliness in Surgical Operations," by Dr. R. Stansbury Sutton, of Pittsburg, Pa.; "Some Points Connected with the Subject of Dysmenorrhœa," by Dr. C. D. Palmer, Cincinnati; "An Unusual Form of Abdominal Tumor," three cases, by Dr. Thaddeus A. Reamy, of Cincinnati; "Is Extirpation of the Cancerous Uterus a Justifiable Operation?" by Dr. A. Reeves Jackson, of Chicago; "A Biographical Sketch of Dr. Nathan Smith, Founder of the Dartmouth Medical College" (being the President's address), by Dr. Gilman Kimball, of Lowell, Mass.; "The Management of Accidental Puncture and other Injuries of the Gravid Uterus as a Complication of Laparotomy," by Dr. Charles Carroll Lee, of New York; "A New Method of Operating for Fistula in Ano," by Dr. Edward W. Jenks, of Chicago; "Ergot: The Use and Abuse of this Dangerous Remedy,"

Campbell, of Augusta, Ga.; "Remarks on Chronic Abscess of the Pelvis," by Dr. William H. Byford, of Chicago. A discussion on "Death after Labor" will be opened by Dr. Campbell.

Correspondence.

FEMALE MEDICAL EDUCATION FROM A WOMAN'S STANDPOINT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In response to your Canada correspondent, in your issue of August 25th, allow me to say that

"He either fears his fate too much,
Or his deserts are small,"

who feels it necessary to his own safety as a practitioner to decry the medical education of women.

In your correspondent's statement that "exception was taken by those ladies to some remarks made by the lecturer on physiology," I can see nothing to indicate that those same ladies, or ladies in general, are, therefore, unfit subjects for the study or practice of medicine; nor can I see in the fact that "the men" (your correspondent makes a nice distinction in not calling them *gentlemen*) "in the class became noisy and made statements that greatly offended the ladies," any special or superior fitness on their part.

It is not worth while to argue the point whether co-education will or will not work, when we see conspicuous instances of its success increasing around us; but we pass on to his gravely expressed foreboding that "there cannot be any doubt in the minds of all who think calmly on the matter, but that these young female doctors will locate on our streets, and in our villages and towns." And pray what if they do? Will the public morals be wrecked in consequence? The social scientist, if *he* "think calmly on the matter," will doubtless tell us society is better for a young woman "locating on our streets" to practise legitimate medicine, than if forced by the closure of all avenues of respectable work she "walk" that same street for bread. Our friend shows lack of knowledge of the number of women who have gone out as medical missionaries, of the constantly increasing call from the mission fields for more workers, and of their great usefulness there. A letter written me in 1880 by a former pastor, a prominent Presbyterian divine, contains this statement: "I have a friend in India, a medical missionary, who has had much success, having had five thousand cases among the Indian women in ten years." Surely that woman has found her work, and is doing God and humanity better service than by devoting her immortal energies to making rick-rack trimming for her dresses.

In answer to the scathing remark that "it is all a question of dollars and cents with the ladies who wish to secure medical qualifications," I can only say that whenever society reaches that happy stage of gallantry to our sex that the tradesman and artisan refuse to accept from us an equivalent of "dollars and cents" for their work and their wares, doubtless the percentage of women who practise medicine from philanthropy, pure and simple, will more nearly approximate that of the men in the profession who decline all fees.

"The move is very unpopular with the profession at large in this country." I would suggest that our progressive physicians are not opposed to it, but willing to see it stand or fall on its own merits. Its unpopularity is mainly among those whom Charles Reade so aptly describes as "pig-headed beyond belief."

That it is not unpopular with the laity, who, after all, are the true arbiters in the matter, is shown in the amount of work women are doing throughout the land.

From the nature of things the practice of women must be more limited than that of men has been. We seek only the privilege of treating the ills of our own sex, and in the field of gynaecology and obstetrics who shall deny that we have fit place.

In accordance with that sure law of supply and demand, just so long as sensitive women prefer to consult competent physicians of their own sex for the ills peculiar to their sex, just so long will the demand be met by competent ladies, educated, if not in Kingston or Toronto, then in New York, Philadelphia, Ann Arbor, Syracuse, Paris, Vienna, etc. The world moves.

CAROLINE S. PEASE, M.D.

TROY, N. Y.

Reviews and Notices.

TREATMENT OF DISEASES OF INFANCY AND CHILDHOOD, with over four hundred Formulæ and Prescriptions, as exemplified in the services of Drs. A. Jacobi, J. Lewis Smith, Alonzo Clark, Austin Flint, W. A. Hammond, A. L. Loomis, W. H. Thomson, J. H. Ripley, T. Gailard Thomas, J. R. Leaming, F. Delafield, L. A. Sayre, C. R. Agnew, L. Duncan Bulkley, Beverley Robinson, R. W. Taylor, G. H. Fox, F. N. Otis, A. A. Smith, E. C. Seguin, F. A. Burrall, E. G. Janeway, F. H. Bosworth, A. H. Smith, C. E. Billington, G. M. Leferts, etc., etc., and in the Hospitals of New York City. By CHARLES H. GOODWIN, M.D. New York: C. H. Goodwin, M.D., 245 West Fifty-third Street. 1883.

The success which we predicted for the author's previous manual on treatment of heart and lung diseases has been realized, and has led to the preparation of this companion volume. This excellent little book is not a mere jumble of formulæ thrown together hap-hazard, but is a systematized and well-ordered collection of the favorite prescriptions of some of the best-known physicians in this city. Each subject is prefaced by a short explanation of the rationale of the treatment followed. While heartily disapproving of the use of ready-made prescriptions, we still think that the publication of formulæ such as this book contains is of value as giving in brief the matured views of men of wide experience in the treatment of disease. Such a book as this is naturally used for the most part as a ready reference manual, and we think its value in this respect would have been greatly enhanced by an index arranged alphabetically instead of by groups.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA at its Thirty-fourth Annual Session, held at Norristown, May 9, 10, and 11, 1883. Vol. XV. Philadelphia: Published by the Society. 1883.

This volume is excellently printed in clear type and neatly bound in cloth. It contains a number of good papers on a great variety of topics. One hundred pages of the Transactions are taken up with reports of very little interest from the County Societies. The volume also contains the circular of the Society for Instruction in First Aid to the Injured, of New York City, which was ordered by the Society to be printed after the report on Surgery.

PHYSIOLOGICAL CRUELTY; OR, FACT VS. FANCY. An Inquiry into the Vivisection Question. By PHILANTHROPOS. 8vo, pp. 156. New York: John Wiley & Sons. 1883.

In this work the author has presented the chief established facts and the principal arguments on the subject of vivisection. The text is, in general, quite accurate in

detail, without evidence of partizanship, and is well worth the attention of the profession. Certain of the more obvious statements which have appeared in print are touched upon; but, as a rule, the numerous popular questions raised upon this matter, and the various results arrived at are avoided. An appendix is also added containing further information on special points.

Reports of Societies.

STATE MEDICAL SOCIETY OF VIRGINIA.

Fourteenth Annual Session, held at Rockbridge Alum Springs, Va., September 4, 5 and 6, 1883.

(By Telegraph to THE MEDICAL RECORD.)

THE Fourteenth Annual Meeting of the Medical Society of Virginia convened in the ball-room of the Grand Hotel, Rockbridge Alum Springs, Rockbridge County, Va., at half-past eight Tuesday evening, September 4th, the President, DR. WM. D. COOPER, of Morrisville, in the chair.

REV. DR. J. J. LAFFERTY, of Richmond, Va., opened the meeting with prayer.

The Naval Academy band from Annapolis, attached to the hotel for the summer, played at intervals during the evening.

The address to the public and profession was delivered by DR. K. EDGAR CHANCELLOR, of Charlottesville, and was devoted to consideration of

THE DIFFERENT MINERAL WATERS OF THE WORLD.

He stated that out of the 876 natural mineral waters of the United States, only 300 had been properly analyzed and classified, and in the course of his address showed plainly the points of difference between natural and artificial mineral waters. He pointed out the manner in which the pure water is changed to mineral waters in the ground, and closed with the reasons for the natural production of hot or thermal waters.

Besides the Society members, a large number of ladies and gentlemen, guests at the hotel, were in attendance.

The Committee on Nominations reported 39 names of physicians for election to fellowship, all being afterward duly elected by the Society.

On Wednesday, September 5th, the Society met in the ballroom of the Rockbridge Springs Hotel, at 10 A.M., and, after opening the session, DR. WM. D. COOPER read the Annual Address of the President, his subject being

THE INDIVIDUAL RIGHTS OF PHYSICIANS,

in the course of which he pointed out the very limited protection afforded the profession by the State of Virginia, and gave some exceedingly valuable suggestions concerning the proper mode of action for redress.

DR. JOHN R. WHEAT, of Richmond, then read the report on Advances in Anatomy and Physiology, and confined himself mainly to a consideration of

THE ANATOMY AND PHYSIOLOGY OF THE MALE URETHRA.

He stated his belief that the surgery of the urinary passages will have made marked progress when it has the boldness to give the

PREFERENCE TO THE USE OF STRAIGHT INSTRUMENTS OVER CURVED SOUNDS, CATHETERS, ETC.

DR. A. M. FAUNTLEROY, of Staunton, made an exhaustive report on Advances in Chemistry and Pharmacy, considering fully the possibilities of the

ARTIFICIAL MANUFACTURE OF A NUMBER OF VALUABLE DRUGS

which now are only obtained in nature. He believed that the day was not far distant when quinine would be manufactured by the chemist without the necessity of

handling cinchona bark. He recommended the use of the tonka or vanilla bean as being by far the best method of subduing or

COVERING THE ODOR OF IODOFORM.

The report was concluded with a detailed description of the properties and employment of convallaria maialis.

DR. M. G. ELLZEY, of Washington, read the report on Advances in Obstetrics and Diseases of Women. He advised against

THE TOO COMMON USE OF STYPTICS IN THE UTERUS, and made an eloquent appeal for

LESS FREQUENT EMPLOYMENT OF FORCEPS.

He spoke against the growing institution of private hospitals for women, and believed that they were often no better and sometimes not as good for lying-in purposes as a room in a comfortable home. He laid down certain rules as regards

PERSONAL DISINFECTION ON THE PART OF THE OBSTETRICIAN,

strongly urging greater care in this respect. He believed that pessaries are often unnecessarily employed, and related a recent case of death following

BLOOD-POISONING PRODUCED BY ULCERATION FROM A PESSARY

introduced in 1860.

DR. WM. H. COGGESHALL, of Richmond, Va., made a report on Advances in Diseases of Children, making special mention of

THE SUCCESSFUL TREATMENT OF CANCRUM ORIS WITH SUBNITRATE OF BISMUTH,

by Dr. McGuire, of New York. He described the mode of reducing congenital phimosis, when stenosis does not exist, by manipulation, as practised by Dr. Willard, of Philadelphia, and after an extended account of the present treatment of children's diseases, closed with a brief recitation of the points of relationship between membranous croup and diphtheria. The paper will appear in a future number of THE MEDICAL RECORD.

DR. McDONALD, of West Virginia, desired that the subject of each paper should be discussed, and after an informal debate, it was decided that any member who wished could speak upon any part of the papers read.

Drs. McDonald, Parker, Hume, Field, and others discussed some of the points presented in Dr. Ellzey's paper.

In the evening DR. THOMAS H. HOWARD presented for the inspection of the Society

A LARGE NUMBER OF BONE SEQUESTRA,

weighing from half a grain to half a drachm each, which had exfoliated from the external table of the skull after fracture during a period extending over four years. The female patient from whom they were taken is now living and in good health, over fifty years of age. The doctor gave a full history of the case, which was peculiar, every piece of bone being

EXTRACTED THROUGH THE EAR.

There was no history of traumatism except that the patient received a lightning-stroke a year before the first piece of bone was discovered.

DR. ELLZEY read a volunteer paper on

THE THERAPEUTIC QUALITIES OF THE RAWLEY SPRINGS WATER,

stating that the peculiar chalybeate water of this spring was not duplicated anywhere else in America, the only localities where a like combination can be found are at Schwalbach and Tunbridge Wells in the Old World. He gave a clinical report of a number of cases of depraved and impoverished blood conditions relieved and cured by the use of this water.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 27, 1883.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

(Continued from p. 249.)

DR. FERGUSON presented a specimen of

ANEURISM OF THE HEART.

The patient was a male, fifty-four years of age, a native of Ireland, married, and a clerk by occupation. Both his parents lived to old age, although his mother was troubled with asthma for many years. He was quite well until April, 1882, when he began to suffer from shortness of breath, and at times cardiac palpitation. These symptoms, however, were not severe until one month previous to his admission into the New York Hospital on the 31st of March, 1883. Then he became quite weak, his feet began to swell, and he passed but a small amount of urine. He suffered from severe dyspnea, cardiac palpitation, irritability of the stomach, and ocular disturbance, together with a cough accompanied by a frothy mucous expectoration. He gave an alcoholic history. On admission he was fairly nourished, feet and legs oedematous, cardiac action and respiration labored. The heart-sounds were roughened, but there was no bruit. He was passing twelve to sixteen ounces of urine a day.

Under treatment the first few days in the hospital his condition improved. Later on in the month of April he complained of great weakness, his respiration being much embarrassed and his legs, scrotum, and penis very oedematous, his abdomen was also distended with fluid. Stimulants and diuretics gave him only temporary relief.

The first week in May he was aspirated, sixty-three ounces of fluid being removed from the peritoneal cavity. After respiration his breathing was much relieved and he was passing at the time twenty-five to thirty ounces of urine a day. His dyspnea continued at times slight but occasionally very severe. On the 17th May he was again aspirated and 108 ounces of clear serum drawn from his peritoneal cavity, without any relief to his respiration or heart action. He was delirious at times and suffered greatly from dyspnea. His heart action was weak and irregular, ranging from eighty to ninety beats in a minute, his respiration forty to fifty, and his temperature 99°, or normal. The urine contained considerable albumen and tube-casts of the granular and epithelial variety.

At the post-mortem examination there were 3,400 c.c. of clear serum in the pleural cavity. There was no evidence of peritonitis. In the right pleural cavity there were 1,350 c.c. and in the left pleural cavity 1,300 c.c. of clear serum. The kidneys are not much reduced in size; their capsules are not adherent; their surfaces are smooth except the presence of a few small cysts. The organs in the recent state were much congested. The markings were obscure and the epithelium lining the convoluted tubules throughout, and the straight tubules in places, had undergone fatty metamorphosis. There were many atrophied glomerules, and thickened vascular walls, as well as tube-casts both in the cortical and medullary portions of the organ. The heart is large; all its cavities, especially its left ventricle, are dilated. The left ventricular wall is hypertrophied, except anteriorly near the apex, where it is very thin and made up almost entirely of fibrous tissue.

In this location the ventricular wall is about one-fourth of an inch in thickness, and is lined by a clot of fibrin firmly adherent to the wall of the heart and is similar to the clots found in aneurisms. The endocardium of both ventricles is thickened, and the left ventricular wall throughout contains a great deal of fibrous tissue. The interventricular septum is normal.

The muscular fibre of the heart on microscopic examination did not contain fat.

DR. GERSTER presented the uterus and appendages removed from a woman thirty-seven years of age, who had suffered for about one year from profuse menorrhagia and continuous metrorrhagia. The patient had never been pregnant, but had been married four years. She had not reached the menopause. The menorrhagia and metrorrhagia were believed to be due to uterine fibroids. Her general condition became seriously reduced, and at times she was so weak that upon slight exertion she would faint. All the ordinary means had been resorted to for producing involution of the fibroma without avail. Finally Dr. Tauszky, under whose care the patient had been, kindly referred her to Dr. Gerster, and on examination he found in the median portion of the abdominal cavity a hard, solid tumor, about the size of the uterus in the seventh month of pregnancy, freely movable in all directions, and smooth over its entire surface. There was evidence of a slight amount of ascites. From abdominal palpation and the fact that the vaginal portion freely followed movements imparted to the tumor, it was thought probable that the swelling occupied the uterus itself. The ovaries were not detected by palpation. It was evident that the woman would soon die unless relieved in some way, and it was determined to give her a chance by attempting to remove the tumor entirely by the abdominal section. Accordingly, after preparatory treatment, the operation was performed on June 7th. The preparatory treatment consisted in the use of laxatives with rectal and the methodical use of vaginal injections of an antiseptic fluid. The patient was etherized and a small incision made in the abdominal wall somewhat below the umbilicus and in the median line. The tumor at once presented itself, and on introducing the fingers into the abdominal cavity the ovaries were readily felt attached to it. The neck of the uterus was found rather slender, and Dr. Gerster thought it would not be difficult to secure it as a pedicle; the tentative incision was therefore extended upward to two and one-half inches above the umbilicus, with a view to everting the tumor as rapidly as possible, and then close at once temporarily the upper part of the incision by silver-wire sutures, leaving an opening in the abdominal wall only sufficiently large to enable him to treat the neck of the tumor, thus guarding against the protrusion of the intestines. An elastic ligature was thrown about the broad and round ligaments and the tube. Another elastic ligature was applied centrally toward the uterus, and the intervening tissues were divided by the actual cautery. This was done on both sides. Having thus secured the vessels leading to the tumor he placed an elastic ligature about the neck of the growth itself and clamped it with lead. The tumor was now cut away at some distance above the ligature with a small amputating knife. His first idea was to strip up the peritoneum and to place an elastic ligature beneath it, but the pedicle was so small that he decided to treat it like the pedicle of an ovarian tumor. The cut surfaces were seared with the thermo-cautery, iodoform was dusted over the stump, and the pedicle was dropped into the abdominal cavity. Except the blood which was lost from the tumor itself, not a drop of hemorrhage occurred save that from the external incisions which was exceedingly slight as it was promptly controlled. No blood whatever entered the peritoneal cavity. The tumor having been removed, and the pedicle treated, the temporary sutures in the abdominal walls were removed, the edges of the peritoneum stitched together by a continuous catgut suture, the edges of the abdominal incision brought together by deep silver sutures, and the ordinary antiseptic dressing applied. The patient's pulse, which before the operation was rather weak, varying from 90 to 96, rose to 108 during the operation, and, after the anæsthesia ceased, to 116 to 118, and remained at this high rate. She complained from the very first, after coming from under the influence

of the anæsthetic, of extreme thirst, which Dr. Gerster regarded as a very ominous symptom. The temperature was normal up to a few hours before death. The patient did not at any time complain of pain, and there was no tympanites; up to twelve hours after the operation there was no nausea or vomiting, but subsequently nausea was present until death occurred. The patient died in collapse with a thready pulse, but no pain whatever, the respirations remaining normal nearly to the end. At the autopsy the abdominal incision was found nearly in a normal condition, union by first intention had occurred throughout except at the lower angle, where about three drachms of purulent fluid had collected. The incision through the peritoneum had completely healed by first intention. The bowels were found in the same collapsed condition that they were in at the close of the operation. The peritoneum itself was normal. The pedicle was absolutely unchanged. The ligature which had been applied to it was in the position in which it was left. There was no evidence whatever of inflammatory process within the abdominal cavity. The uterus, containing a large fibroid tumor, together with the pedicle, altogether weighing seven pounds, the cervix, and a portion of the vagina were presented. Dr. Gerster believed that death was due to the anæmic condition of the patient, and the shock of the operation probably hastened by the otherwise not high fever due to suppuration of the external wound. He believed that the formation of the purulent fluid which was found at the lower angle of the abdominal incision was due to septic infection; for complete antiseptic precautions had been taken, all instruments and utensils used had been disinfected, also the hands of all the assistants and of the nurses; but he was convinced that while he was closing the external incision some fault in the management of the sponges must have been committed. It was in the external incision that the suppuration occurred, as shown by the autopsy, either the sponges or the hands of the nurses who assisted at this stage of the operation, or both, had not been rendered antiseptic.

The Society then went into executive session.

AMERICAN DERMATOLOGICAL SOCIETY.

Seventh Annual Meeting, held at Lake George, August 29, 30, and 31, 1883.

WEDNESDAY AUGUST 29TH—FIRST DAY—MORNING SESSION.

The Association met at the Sagamore House, and was called to order at 10.30 o'clock by the President, DR. R. W. TAYLOR, of New York, who welcomed the members with a few appropriate remarks and then proceeded immediately to the scientific business.

The first paper was read by DR. H. G. PIFFARD, of New York, on

THE TREATMENT OF ACNE.

The term acne was restricted to inflammatory affections of the sebaceous glands. This affection never begins, and relapses never occur, without sufficient cause, and the first indication is to seek for and, if possible, remove the etiological factor, whether gastric, intestinal, uterine, etc. It is only partly true that it is an incurable disease. It is subject to repeated relapses. It can be cured temporarily quite easily; its course may be aborted and often shortened. Dr. Piffard then related the history of a case occurring in a patient who suffered from ovarian trouble, the removal of which was followed by a cure of the acne. He also referred to a case of chronic incurable organic uterine disease in which a severe acne existed that persisted despite treatment, and stated that in such instances all that could be reasonably expected was temporary alleviation.

Acute acne vulgaris.—The drug which he had administered internally with the most satisfactory results was the calx sulphurata, in small doses to be discon-

tinued as soon as good effects are manifested. Next in efficacy was the bromide of arsenic in doses of from $\frac{1}{100}$ to $\frac{1}{50}$ of a grain—a one per cent. alcoholic solution administered in doses of from one to two minims (not drops) in a wineglass of water upon an empty stomach. As the acne improves lessen the doses. He had found the former drug most serviceable in the lymphatic variety and the latter in acne of the florid type. External treatment: depletion by incision and bathing with warm (not hot) water; in simple cases puncture the papules, and puncture each fresh papule as it appears. The next external application recommended was frequent bathing with *very hot water*. In the pustular variety the pustules should be punctured, the contents squeezed out, and the parts bathed with *hot water* to reduce the congestion. Other external applications mentioned were soothing agents, such as belladonna and stramonium—belladonna liniment mixed with benzoated lard, sometimes ammoniate of mercury; fluid extract of stramonium, made from fresh leaves gathered in the autumn, incorporated in benzoated lard in the proportion of 3j. to 5j.

Subacute acne vulgaris.—Internal treatment by the use of calx sulphurata, but in much larger doses than in the acute form, and continued until the physiological action of the drug is manifested by increased activity of the eruption, perhaps by increased number of the lesions, and perhaps by a tendency to suppuration. In occasional cases he used mercury (corrosive sublimate), iodide of potassium, and ergot. In external treatment the principal indication is the employment of applications which produce an irritant or substitutive inflammation, such as green soap, sulphur, biniodide of mercury, corrosive sublimate, which act as irritants and are followed by hyperæmia with swelling, etc. When the action has reached a proper limit, discontinue the remedy and permit the parts to return toward the healthy state. The strength of these applications must be varied according to the effects produced; it is well to begin with applications of moderate strength.

The author of the paper then referred to the views of the Vienna and French schools, and to the practice of English and American dermatologists.

With regard to ergot, as recommended by Dr. Denslow, of New York, given in doses of twenty to thirty grains twice or three times a day and continued for several weeks he had seen some cases in which benefit followed its use.

Comedones.—These yield only to mechanical treatment. Remove them by pressing upon the surrounding skin, and if the sebaceous plug does not readily come out, enlarge the mouth of the duct with a fine needle.

Acne indurata, whether acute or subacute, may be regarded as an aggravated acne vulgaris, and the principles of treatment are substantially the same as in acne vulgaris. The most striking results he had seen follow the use of ergot had been in this form of the disease.

DR. ATKINSON, of Baltimore, had used the sulphide of calcium faithfully, but had failed to obtain the favorable results, which from time to time had been reported. He had used ergot, but also without noteworthy benefit. Whatever of benefit he had obtained had been by the use of local applications, together with such remedies and measures as were indicated to correct or remove those disorders, gastric, intestinal, uterine, etc., which were generally supposed to be causes of this local inflammation.

DR. VAN HARLINGEN, of Philadelphia, had used with considerable benefit, in eight or ten cases of *comedones*, the following smeared over the elevations: Official acetic acid, two parts; glycerine, three parts; and kaolin, four parts.

DR. W. T. ALEXANDER, of New York, had used calx sulphurata with considerable benefit, but usually only in the pustular variety. On the other hand, he referred to a case in which the remedy, administered in small doses four times a day, exhibited lack of power to arrest sup-

puration. The only good effect he had seen follow the use of ergot, was a seeming diminution of the redness, but only so long as the drug was being taken.

DR. SHERWELL, of Brooklyn, did not employ the sulphide of calcium. He had obtained sufficiently good results by the use of external applications with the use of internal remedies, especially ergot. He had found cannabis indica of great benefit in acute forms of the disease tending to the pustular state. He associated acute pustular acne with menstrual disturbances very decidedly, and always employed ergot—moderately during the period, more pronounced between the periods, especially just before and just after the occurrence of one. He could speak with certainty of the beneficial effects produced by this drug in this form of acne occurring in females, and had thought benefit followed its use in males. In the rosaceous form of acne he had found ergot especially beneficial. He regarded its use as empirical, in all probability; at least, did not accept Dr. Denslow's views that it acts upon the muscular tissue of the skin.

DR. GRAHAM, of Toronto, had found calx sulphurata useful in suppurative diseases, whether acne or the formation of abscess.

THE PRESIDENT said that the interest in the paper centred upon the more or less importance of local and constitutional treatment. He wished to again put on record his belief that *curative* influence is exerted only by local measures, and that internal treatment is merely subsidiary. As regards the reciprocal relations between acne and uterine affections, he had not yet reached any definite conclusions. That they existed at the same time in the same patient was well recognized, but he had not yet become satisfied as to whether the acne actually was caused by the uterine disorder.

In the treatment of acute acne he had placed great reliance upon alkalies and diuretics; one or two drachms of Rochelle salt with thirty grains of the acetate of potash in a wineglass of water three times a day. In the hyperæmic form he always obtained benefit by this medication, and also in the indurated variety. Besides puncture, recommended by Dr. Piffard, he had been accustomed to apply liquor hydrarg. pernitratiss—one to eight of water—once or twice a day. He had also used with marked benefit, in that form, also accompanied with rosacea, one-half ounce of chrysarobin to one ounce of flexible collodion; pencil patches. The use of this remedy necessitates sequestration of the patient for some time. He had also obtained benefit in the treatment of acne indurata by the use of Donovan's solution, pushed until ten or twelve drops are taken at a dose, three times a day.

In his hands ergot had not cured a single case. It relieves the hyperæmia but has no effect upon the induration. In the various forms of acne he had obtained the most gratifying results from the use of mercurial ointment—one to eight of vaseline—or ointment of biniodide of mercury.

DR. STELWAGON, of Philadelphia, had obtained good results from the use of a lotion composed of sulphate of zinc, ʒj.; sulphuret of potash, ʒj.; water, ʒiv.

THE PRESIDENT and DR. SHERWELL had used this lotion with good results. The President had used an ointment of iodide of zinc, five to thirty grains to one ounce of vaseline or lard, with excellent results.

DR. GRAHAM, of Toronto, then read a paper on

GENERAL EXFOLIATIVE DERMATITIS.

The author of the paper first directed attention to the significance of the term, and then made brief allusion to the literature of the subject. He had collected thirty-four cases, of which eleven terminated fatally, ten recovered entirely, and in seven the recovery was partial or the result was not known. In eight cases the disease ran an acute course, not lasting longer than a few weeks, and in twenty-five it was chronic, lasting for months or

years. He had had under observation four cases, two of which were of a chronic character, and two were acute and recurrent. In the third case the seizures occurred at various seasons of the year, and in the fourth case the first three took place in summer and the fourth in March. In both the disease ran a very similar course, except that in the latter there was at the beginning a vesicular eruption, whereas in the fourth no such lesion occurred.

It is probable that many cases of general exfoliative dermatitis have been mistaken for scarlet fever. The principal features of the disease may be considered under three heads: (1) general hyperæmia; (2) general exfoliation of the epidermis; and, (3) severe constitutional symptoms appearing at various times throughout the attack, and in many instances a tendency to a fatal result. In some cases preceding the hyperæmia and exfoliation there is a serous exudation. From his observations, the author of the paper agreed with Dr. Baxter and Dr. Jamieson in the opinion that the term general exfoliative dermatitis may be applied to all the cases which are generally described under the names pityriasis rubra and pemphigus foliaceus, as well as to other cases which cannot be classed with either. There are two principal sub-divisions of the affection: 1, acute; 2, chronic. Of the latter there are two varieties: (1) in which hyperæmia and exfoliation exist, and it might be called dermatitis exfoliatum rubrum; (2) in which a serous exudation, in the form of bullæ, precedes the exfoliation, and this might be called dermatitis bullosa et exfoliatum. The former variety would include pityriasis rubra and the latter pemphigus foliaceus. The acute form, although often single, has a strong tendency to recur, influenced by season or outward circumstances. The recurrences may be accounted for from individual peculiarities.

DR. HARDAWAY, of St. Louis, had under observation one case of five years' standing, which manifested some improvement under the internal use of the tincture of iron; all other methods of treatment having failed. He had seen one quite acute case; another occurring in an infant; another occurring in a young lady, of neurotic family, and since the attack she had suffered during the last seven years from frequent occurrences of bright hyperæmic spots, varying in size from that of a silver dollar to that of the hand, exceedingly hot and throbbing to the touch, and *without* exfoliation.

DR. ATKINSON, of Baltimore, thought it impossible to describe a distinct disease that could be called pityriasis rubra. Again, it was desirable to find some name to apply to certain cases, and he thought general exfoliative dermatitis was as good as any, perhaps. He believed that there is a very wide range in these cases, but that the disease always depends upon trophic neuroses, the nature of which we do not understand. Some cases answer to pityriasis rubra; others give patches which are undoubtedly eczematous; and then there are chronic cases of exfoliative dermatitis. He regarded it as important to remember that the skin of certain individuals manifests a marked tendency to become inflamed as the result of the internal use of certain drugs; for example there is a well-marked eruption produced by quinine.

DR. G. H. FOX, of New York, approved of what Dr. Atkinson had said concerning the advisability of including all forms of dermatitis under the general name, and thought it was fallacious to endeavor to make a differential diagnosis clinically. As to pityriasis rubra and eczema, however, he believed there were reasons for making a distinction, and, in many of the cases of general desquamation which are spoken of as exfoliative dermatitis, there is an eczematous process which involves the mucous layer of the skin, and is not a disease of the vascular supply or a primary disturbance of the nervous system, as is pityriasis rubra. He thought Dr. Graham had done well in associating the acute and chronic cases.

DR. P. A. MORROW, of New York, believed the disease to be neurotic in character, and in two cases had seen decided benefit produced by arsenic.

DR. SHERWELL thought an exception should be made with reference to pemphigus foliaceus, as it was sufficiently distinct in character still to be entitled to retain its original name. He accepted Dr. Graham's first division, but not the second.

DR. PIFFARD thought there were three quite distinct affections: (1) pemphigus foliaceus; (2) pityriasis rubra; (3) dermatitis exfoliativa. He admitted that it was sometimes difficult to make a differential diagnosis, but that fact could not be used as an argument in favor of a general name.

DR. GRAHAM said he had doubted the propriety of placing pemphigus foliaceus under the head of general exfoliative dermatitis, but at the same time the two conditions had so many features in common that he had ventured to do so.

THE PRESIDENT regarded the further study of the three affections mentioned by Dr. Piffard as very important. He then called attention to two cases. The first occurred in a woman thirty years of age, a widow, the mother of one child, and a sufferer from chronic malaria, who had fifteen attacks, produced by taking either quinine, cinchonine, or elixir of calisaya. The second case occurred in a boy nineteen years of age, who had been under observation five months. The patient had been exhibited to the New York Dermatological Society, and a history, so far as then given, had been published in the July number of the present year of the *Journal of Cutaneous and Venereal Diseases*. The interest in the case centred in the question whether or not the condition of the skin depended upon syphilis. It was the most remarkable case of exfoliative dermatitis he had ever seen, and was surrounded with grave doubt concerning its etiology. Dr. Taylor's description of the case was accompanied by several photographic illustrations.

DR. STELWAGON, of Philadelphia, then read a paper on

IMPETIGO CONTAGIOSA.

The author of the paper first referred to the individual nature of this affection, and the correctness of the views advanced by Tilbury Fox. He believed there was no evidence that the disease is in any way related to ring-worm; also that it does not follow contagious pustular affections as claimed by Dr. Hyde, of Chicago; further that a pustular disease cannot be modified by a contagious disease; nor, in case that such a modification might be produced that the modification could propagate itself. If the disease is not a modification of some other affection the conclusion must be reached that the process is an independent one, and the individuality of the disease must be admitted. The eruption has contagious properties. He doubted the truth of the idea that it is of fungous nature. In five hundred microscopic examinations he had been unable to find the fungus described by Dr. Piffard except in three instances, and regarded the fungi when found as in all probability adventitious. The view that the affection is a general systemic disease with cutaneous manifestations seemed to him to be the most tenable that could be offered. This view is sustained in a measure by the writings of Tilbury Fox, and there are several reasons which support the theory. Aggregated experience proves the existence of prodromic symptoms, and ordinarily it runs a short but definite course. The eruption is auto-inoculable, which explains the existence of new patches. There are several facts which are against the supposition that the disease follows vaccination. The author's conclusions were: 1, that it is a separate and distinct disease; 2, that it is not parasitic; 3, that it is not related to vaccination; and 4, that it is an acute systemic disease with cutaneous manifestations and probably due to a specific poison.

DR. HARDAWAY regarded the fact that the disease occurs epidemically as a strong argument in favor of its being an independent affection.

DR. ATKINSON felt very uncertain concerning the individual nature of the disease.

DR. ROHE, of Baltimore, did not recollect that he had seen a case during the last two years. That the pus of impetigo contagiosa is inoculable he was quite sure; that it is inoculable upon healthy individuals; and that successive inoculations become weaker. He had been unable to find a fungus. That it is an independent disease he was moderately certain; but that it is found only after contagious diseases and in individuals who are not in good health, as suggested by Dr. Hyde, he did not believe, yet what the exact nature of the disease is he did not know.

DR. G. H. FOX thought all would agree that the pus is inoculable, that it does not depend so much on the character of the soil as on the character of the pus; and that the peculiar pustules which result are not to be classed as pustular eczema. He thought Tilbury Fox was unwise in giving the affection a new name. He had generally studied it as a disease of the skin; but regarded the suggestion that it is constitutional as worthy of attention. Dr. Fox was also inclined to doubt the proposition that it has no connection whatever with vaccination; but exactly what the relation is he was unable to say. With regard to pediculosis, it might not produce an eruption, but certainly it would cause the spread of one.

DR. GRAHAM had always regarded impetigo contagiosa as a distinct disease, and was inclined to agree with Dr. Stelwagon concerning its nature.

DR. PIFFARD preferred to go back to the old name. He had a series of cases in different families, and in every instance the first in each series appeared shortly after vaccination, and the other cases followed. As to its parasitic nature he was still inclined to hold to that view, although no one had found a definite parasite in the vesicle; fungi had been found in the crusts only, and several who had found fungi had found different ones. He found, at the time he made his observations, a permanent fungus, the same as he found in vaccine, and similar ones have not been described in connection with any other form of disease. If it was a common crust fungus he should be forced to give up the connection of the disease with vaccination. A point in favor of its parasitic nature is the fact that it is cured so readily with parasitocides. He had not regarded it as a self-limited disease, but thought the explanation given by Dr. Stelwagon was a very ingenious one.

THE PRESIDENT was a firm believer in the individuality of the disease. He could not regard it as a systemic affection. The existence of a prodromal fever was exceedingly doubtful. In sixty cases he had observed, the disease began locally about the face or nails in every instance, and afterward different parts of the body were inoculated. He thought the systemic reaction could be easily explained by the existence of an eruption. He believed it spreads by immediate contagion. He believed the disease originated in some form of pus which lodges upon the skin, then develops a pustule, and from this it is communicated to others, or to other parts of the body.

DR. FOX had had cases which did not yield readily to treatment, and had remained obstinate for two or more weeks.

DR. STELWAGON said that sometimes several weeks were required to get rid of the disease.

DR. ROHE said he did not wish to endorse the view that the disease is systemic, the same as scarlet fever, etc., but simply wished to say that he regarded it as inoculable locally.

DR. HARDAWAY had not seen the disease associated with vaccination.

The Association then adjourned to meet at 8 P.M.

WEDNESDAY—FIRST DAY—EVENING SESSION.

The Association was called to order at 8 P.M. by the President.

DR. ATKINSON, of Baltimore, then read a paper entitled

A CASE OF MULTIPLE CACHECTIC ULCERATION.

The case occurred in a female child, mixed white and black, without any evidence of syphilis, and the effect of mercury, ergot, and scurvy, as well as diabetes, could be excluded. The symptoms summarized were, papillation, vesiculation, followed by superficial destruction of tissue and progressive ulceration which destroyed all the tissues, even the bones. At no point did gangrene in mass occur. It was not entirely symmetrical. Motion and sensation were impaired, but there was not complete paralysis of either. There was no evidence of itching or pain. Distinct symptoms of vaso-motor disturbance were not observed. Dr. Atkinson thought there could be no doubt that his case belonged to the group named by Oscar Simon multiple cachectic gangrene, and that it was one of the trophic neuroses.

DR. VAN HARLINGEN reported a case of trophic neurotic gangrene occurring after amputation of the thigh.

THE PRESIDENT reported two cases seen with Dr. W. H. Draper, at the clinic at the College of Physicians and Surgeons. The first was a puny child, six months old, that had an ulcer upon the back which began as a water-blister. Despite treatment it extended and became very large, destroying the skin down to the muscles. Under generous diet and tonics it ultimately recovered.

The other case occurred in a woman thirty years of age, married, who had never had children, and never had taken ergot. She came with each finger on both hands in a bluish congested condition, but no bullæ existed. There was swelling of the tip of the nose and upon it was a bulla, which broke down into an ulcer, involving all the tissues down to the cartilages. The patient lost fully one-half of every finger, the thumbs escaping. She finally recovered. The only etiological factor that could be reached was excessive indulgence in buckwheat cakes.

EXPERIMENTS IN THE USE OF NAPHTHOL.

DR. VAN HARLINGEN read a paper with the above title, in which he gave the conclusions reached by Kaposi, who introduced the use of the remedy, together with a commentary containing his personal experience in its use. He had found it of great service in scabies, also of some value in the treatment of psoriasis. In parasitic skin diseases naphthol is of but little use, while in eczema and hyperidrosis it is entirely without value.

DR. FOX had used the remedy externally in almost every case where he could possibly employ it, and had become convinced that it falls far short of taking the place of tar. In a few cases of eczema of the scrotum and anus he had obtained very satisfactory results from the application of a five per cent. ointment. For psoriasis of the scalp and face the ordinary white precipitate ointment had served most satisfactorily.

DR. WIGGLESWORTH, of Boston, thought Kaposi did not use naphthol as much as formerly. His own experience corroborated that of Dr. Fox.

DR. HARDAWAY had found it very much inferior to chrysophanic acid in psoriasis and eczema. In the fissured and squamous eczema of the palms of the hands and fingers he had used a fifteen per cent. ointment with good success.

DR. STELWAGON thought it inferior to white precipitate ointment for psoriasis of the scalp; regarded it as very efficient for scabies, and was of the impression that it is now scarcely used in Vienna except in the treatment of this affection.

DR. PIFFARD regarded naphthol as a dangerous remedy.

THE PRESIDENT had used it with good results in scabies, but in psoriasis it had proved inefficient.

DR. G. H. FOX, of New York, then read a communication, entitled

A TRIP TO TRACADIE (LEPROSY),

together with propositions submitted jointly by himself and Dr. Graham, of Toronto. Tracadie is in New Brunswick and has a lazaretto where lepers reside. During this summer he had visited the place, and so also had Dr. Graham, of Toronto, under the direction of the Dominion Government. The lazaretto has at present 24 inmates, 11 males and 13 females, and is under the charge of Sisters of Charity. The disease as seen was partly of the tubercular and partly of the macular variety, and there were three cases which were not leprosy. Some of the cases showed a peculiar skin disease that appeared to be syphilitic in character, although there were no marked lesions of syphilis. As to the white scales, so often referred to, he was struck with one fact, namely—that both forms showed shining silvery scales, very much as found in psoriasis, except not having the peculiar circumscribed form. Many of these patients had papular eczema, which gave them much annoyance. Most of the patients, with the tubercular form especially, presented marked ulceration of the hard palate; in one case there was perforation. Many of the cases presented a well-marked form of dactylitis, without the suspicion of syphilis, but with enlargement of the bones of the toes in one case. Those who had ulceration of the hard palate had also laryngeal trouble, either the peculiar wheezing or complete aphonia. The following were the propositions submitted as a joint communication by Drs. Fox and Graham:

First.—Leprosy is a constitutional disease, and in certain cases appears to be hereditary.

Second.—It is undoubtedly contagious by inoculation.

Third.—There is no reason for believing that it is transmitted in any other way.

Fourth.—Under certain conditions a person may have leprosy and run no risk of transmitting the disease.

Fifth.—It is not so liable to be transmitted to others as is syphilis in its early stages. There is no relation between the two diseases.

Sixth.—Leprosy is usually a fatal disease, its average duration being from ten to fifteen years.

Seventh.—In rare instances there is a tendency to recovery after the disease has existed many years.

Eighth.—There is no valid reason for pronouncing the disease incurable.

Ninth.—Judicious treatment improves the condition of the patient, and often causes a temporary disappearance of the symptoms.

Tenth.—There is a ground for the hope that an improved method of treatment will in time effect the cure of leprosy, or at least that it will arrest and control the disease.

DR. FOX admitted that he had yet to cure his first case, but he did not believe that leprosy is an incurable disease. The treatment adopted in the New York Hospital, consisting in the use of chaulmoogra oil, and large doses of nuxvomica, had afforded a degree of success, and he read a letter received from a patient which showed that the disease in his case had at least been non-progressive for some time.

There is no evidence that either physicians or nurses have acquired the disease by attendance upon those affected with it.

DR. D. B. SIMMONS, who had had a large experience in the treatment of this disease in Japan, was invited to open the discussion. He thought it exceedingly difficult to study leprosy in lazarettos. According to his observation, and the view is fully recognized by the Japanese, the disease manifests itself *first* in the face, and by a peculiar blushing or lividity of the features, especially after taking wine, etc. The development of this peculiar

appearance is at once sufficient to drive the person immediately into exile. Next the anæsthetic symptoms usually are most prominent, anæsthetic spots, without any other manifest change in the condition of the skin or existence of other symptoms of the disease. Then the disease shows itself sometimes upon the ears, sometimes elsewhere, with exacerbations at times, sometimes with fever, bleeding from the nose, etc. His own opinion was that it is decidedly hereditary, but it is exceedingly difficult to reach facts bearing upon this question, because of the prompt exiling of any member of the family who develops the first peculiar symptoms, and subsequent denial that the disease ever existed in the family. He did not regard it as either contagious or infectious, and it is not regarded by the Japanese as contagious. The duration of the disease is exceedingly variable. He had never succeeded in curing a case, nor had he seen a case that had been cured, but almost without exception every patient might be benefited by treatment. Strict attention to hygiene, diet, and cleanliness, aided by the internal and external use of copaiba had yielded the most favorable results he had obtained.

DR. ROHE said that, if the disease is spread by contagion, there is a marked difference in the susceptibility of different persons to its influence; a much more marked difference than exists with reference to any other contagious disease.

DR. WIGGLESWORTH had studied the disease in Norway and Spain as well as in the East, and could corroborate Dr. Fox's views concerning the non-communication of the affection to physicians and nurses. His view was, that while it is inoculable, it is but faintly, if at all, contagious, and not at all infectious. Nor did he see anything in the direction of *white patches* to suggest the existence of the disease.

DR. GRAHAM regarded the disease as inoculable and infectious. He was also inclined to believe that the disease is hereditary, although no case in Tracadie confirmed that belief. He had noted a decidedly marked difference in susceptibility of different persons, as illustrated by one family especially in Tracadie.

DR. PIFFARD accepted the ten propositions. He also referred to one instance in which a physician took the disease and died of it. He thought it was utterly impossible to determine in any given case whether the disease is due to heredity or to infection.

DR. SHERWELL, of Brooklyn, then read a paper on

PAGET'S DISEASE, OR MALIGNANT PAPILLARY DERMATITIS.

He had had two cases, and these with those recorded by Paget, Butlin, Morris, Thin, and Duhring made 27. He had recorded his first case, the first published in the United States, in the January number of the *Journal of Cutaneous and Venereal Diseases*. The author of the paper gave the following conclusions:

First.—The subjective symptoms, itching, burning, are those of an eczema, and not those of an ordinary carcinomatous affection, but they are more marked than in an ordinary case of eczema.

Second.—The objective symptoms are like those of eczema; the discharge is absolutely similar to that of catarrhal affection of the skin, stiffens linen, and forms crusts entirely indistinguishable from those of an impetiginous eczema. The color of the surface is perhaps occasionally more livid, but the border is, in his opinion, not more sharply defined than is common in that trouble. The somewhat elevated appearance of the patch simulates exactly the acutely macerated and swollen conditions of the lower epithelial layers we so frequently find in eczema. Sir James Paget compares the appearance to that of a balanitis, an apt illustration.

Third.—The disappearance of the nipple is spoken of by Henry Morris as a "melting away," a very acceptable term.

Fourth.—The "malignant papillary" feature, as de-

scribed by Thin, was a marked element in his first case; much less in the second. It is a very diagnostic point, and would of itself, he thought, instantly resolve any doubts as between it and true eczema.

Fifth.—The extreme length of time may be noted in his cases, before the appearance of anything like positive evidence of carcinoma. It will be noticed that Sir James Paget gives the limit, as to this, as two years. In Dr. Sherwell's first case twelve years elapsed from attack to death, the latter event not seeming in any way connected with the skin lesion; in the second case considerable over the time mentioned by Paget had already passed.

The Association then adjourned to meet at 10 A.M., Thursday, August 30th.

THURSDAY, AUGUST 30TH—SECOND DAY—MORNING SESSION.

The Association was called to order at ten o'clock, DR. I. E. ATKINSON, of Baltimore, Vice-President, in the Chair.

DR. WIGGLESWORTH, in behalf of Dr. White, presented the statistical report, which was accepted. On motion by Dr. Taylor, a vote of thanks was extended to Dr. Wigglesworth for his most valuable services in performing the work which Dr. White, Chairman of the Committee, had been prevented from doing by reason of absence in Europe.

DR. P. A. MORROW, of New York, then read a paper on

THE PATHOGENESIS OF DRUG ERUPTIONS.

Under this head are included all eruptions caused by either the internal or external use of drugs. There is a difference of opinion as to whether these eruptions should be classed among physiological or among toxicological effects. A large proportion of drug eruptions are the expression of the physiological action of the article used. The term pathogenesis is employed with reference to the close relationship which exists between physiological and pathological effects. Dr. Morrow discussed at considerable length the difficulties encountered in attempting to distinguish between the two effects, and especially when influenced by individual susceptibilities and other modifying circumstances. He then passed to a review of the theories which had been advanced in explanation of the phenomena, such as that a large proportion of these eruptions are produced by the elimination of the drug through the skin, special affinity for cutaneous structures, dynamic action of drugs, all of which had been proved to be fallacious. This was followed by a discussion of the theory of the neurotic origin of drug eruptions, which he believed best explained the phenomena in each case. The paper closed with a reference to the broad meaning of the term idiosyncrasy, as, after all, anomalous eruptions are determined by the individual rather than by the drug. The nervous element predominates in persons who have an idiosyncrasy.

DR. R. W. TAYLOR then read a paper entitled,

POLYMORPHOUS CHANGES OBSERVED IN THE TUBERCULAR SYPHILIDE.

The paper was based upon a case of syphilis presenting rather early tubercular eruption, described in the books as non-ulcerative tubercular syphilide. The eruption was general, symmetrical, copious, and had the characteristics of the secondary eruption, but besides, all the deep-seated peculiarities of the tertiary eruption, so that, in order to place it in its chronological relation, it would be called what the French denominate the intermediate eruption.

The patient was a male, forty-seven years of age. Dr. Taylor gave a detailed description of the changes which took place in the eruption, and illustrated them by plates, colored upon photographs. At one period in the case, the eruption appeared strikingly like psoriasis, and subsequently the appearances of psoriasis rupioides, as illus-

trated by McCall Anderson, and maintained by Fox, a condition which might give rise to the suspicion that, what those authors had called psoriasis rupioides, is only a late form of a papular or tubercular syphilide.

The points of interest in the case were the following :

First.—Its resemblance to psoriasis.

Second.—The colloid degeneration of some of the tubercles concomitantly with the increase of the granulation tissue in others.

Third.—The degeneration of the colloid tissue into pus, and the formation of bullæ.

Fourth.—The evidence offered that true bullæ may appear in a syphilitic subject, though they result from degeneration of tissue, rather than from effusion of serum and pus, as occurs, as a rule, in simple pemphigus.

Fifth.—The development of tubercles having thick, imbricated, conical, epidermal crusts appearing like rupia.

Sixth.—In the suggestion offered by these lesions, that perhaps the psoriasis rupioides of authors is more or less dependent upon syphilis.

Seventh.—The formation of true rupia crusts from the bullæ above spoken of.

Eighth.—The fact that the non-ulcerated tubercular syphilide may be the starting-point of severe and extensive gummatous infiltration.

DR. HARDAWAY related the history of a case of psoriasis rupioides, as described by McCall Anderson, occurring in a non-syphilitic patient. The only departure from the appearance of ordinary simple psoriasis was the heaped-up condition of the scales. The mother of the patient had ordinary psoriasis vulgaris.

DR. ATKINSON remarked that Dr. Taylor's paper was also interesting as showing the power of syphilis to assume nearly all phases and simulate almost all diseases.

PSEUDO-PSORIASIS OF THE PALM.

DR. SHERWELL read a paper on the above subject, in which he said that in using this title he inferentially and necessarily included those lesions invading the structures anatomically analogous, the plantar surfaces. As to whether a psoriasis, pure and simple, ever occurs in the regions named, he had steadfastly maintained the negative.

In conclusion, he would say that he believed a squamous eruption upon the palms (excluding eczema, etc.), resembling psoriasis, always to have a syphilitic diathesis for its base, or one of its bases, and to be *prima facie* evidence thereof. He did not think, however, that if it could be decided, any great change in the general treatment would be effected, but he did believe that an eruption of this nature, in this location, would always in the physician lead him intuitively to the employment of Donovan's rather than Fowler's solution. But even here again the result of treatment would evidently not be diagnostic proof. Dr. Sherwell had seen one case, presented to the New York Dermatological Society by Dr. Bulkley, which almost convicted him that his belief was erroneous, but several of the members expressed grave doubt concerning the absence of syphilis. Dr. Sherwell then gave the history of a case.

DR. W. T. ALEXANDER, of New York, then read a paper on

PSORIASIS AFFECTING THE PALMS,

in which he gave the histories of three cases of the disease occurring in non-syphilitic patients. The paper was illustrated by photographs. Discussion on these two papers was opened by Dr. GRAHAM, who reported two cases of psoriasis of the palms, the only ones he had ever seen, occurring in non-syphilitic patients.

DR. MORROW stated that while psoriasis is extremely rare upon the palms, and while it probably never occurs independent of its development upon other parts of the body, yet clinical facts prove that it may develop upon the palms. He had seen a number of cases of psoriasis of the palms in non-syphilitic patients.

DR. TAYLOR saw the three cases reported by Dr. Alexander, examined the patients, but was unable to find any evidence of syphilis. He had not seen psoriasis of the palms or the body that did not exhibit psoriasis of the nails first. That simple psoriasis can affect the palms he thought there was no doubt. He thought, however, that it had never been seen confined to the palm.

DR. MORROW had seen a case in which the disease was confined to the palm.

DR. ALEXANDER said he had been struck with the evanescence of psoriasis of the palm, and perhaps that was the reason why it was seen so rarely upon the palms. He cited a case in which it appeared and disappeared within a few days without treatment.

DR. SHERWELL said that to prove negative was far more difficult than to prove positive syphilis, and congenital syphilis also formed a part of his theory concerning psoriasis. He had seen simple psoriasis, and then the patient contracted syphilis, and soon afterward psoriasis of the palms developed so repeatedly that he must still believe palmar psoriasis has a syphilitic basis. It might be that the syphilis gives the psoriasis a change, so that it appears in the palms; that view he was prepared to accept.

A paper entitled

A STUDY OF THE COINCIDENCE OF SYPHILITIC AND NON-SYPHILITIC AFFECTIONS OF THE SKIN,

and sent by DR. HYDE, of Chicago, was read by DR. Wigglesworth.

The more precise and exact the study of the symptoms in syphilis, the more clearly will be recognized two facts which are strictly related: 1. Syphilis much more resembles other diseases in its career and its subjection to accidental influences than has been commonly supposed and taught. 2. When syphilis precedes, coexists, or follows other pathological conditions, its unity is preserved, and it rarely undergoes itself, or induces in other diseases, such a modification as distinctly changes the type of the resulting symptoms. The first statement was supported by the following propositions; the second required clinical demonstration:

(a) Allowance being made for a wide field of distribution of its lesions, the study of one hundred consecutive cases of syphilis will convince an unprejudiced observer that such cases resemble each other as closely as do a similar number of consecutive cases of pneumonia, typhoid fever, or chronic interstitial nephritis.

(b) Syphilis is no exception to the general rule that the patient of greatest vigor best endures its penalties.

(c) Syphilis acknowledges subjection to the great accidents which commonly and evidently work changes in all disease-processes in man.

(d) Syphilis, like other diseases, may lurk obscurely in the system, but everything said and done, it must be betrayed by syphilitic symptoms, or we cannot admit its existence.

(e) Vulgar belief to the contrary notwithstanding, cases of syphilis, like those of other diseases, are readily separable into three well-known groups: (1) mild, benignant or self-limited, requiring no treatment; (2) the grave, malignant, when treatment can have little or no effect; and (3) those falling between these two extremes, where judicious treatment is capable of turning the scale in one direction and injudicious treatment in the other.

(f) There is no specific treatment applicable to every case of syphilis, which can be safely employed to the exclusion of all others.

In what followed the author of the paper proceeded to show how far clinical evidence supported the second of the two general propositions, that which recognizes the unity of syphilis displayed in fairly typical symptoms in the subject, who are affected with other diseases more particularly involving the skin. Varieties of suborhœa and comedo are probably found in more frequent co-

existence with syphilis than the other disorders of secretion. Erythema, urticaria, eczema, herpes, the several forms of acne, impetigo, ecthyma, furunculus, anthrax, and the varieties of dermatitis frequently occur in subjects of an active syphilis. Herpes zoster he had not seen in a syphilitic subject. To the subject of the co-incidence of psoriasis and syphilis the author of the paper directed special attention, and gave, with very great detail, the histories of two cases.

The Association then adjourned to meet at 8 P.M.

THURSDAY--SECOND DAY--EVENING SESSION.

The Association was called to order at 8 o'clock by DR. ATKINSON, Vice-President.

The PRESIDENT, DR. TAYLOR, read a paper entitled THE PECULIAR APPEARANCE OF THE INITIAL LESION OF SYPHILIS AT THE EARLIEST PERIOD OF ITS DEVELOPMENT. [See p. 255.]

A paper by DR. DUHRING, of Philadelphia, on THE VALUE OF A LOTION OF SULPHIDE OF ZINC IN THE TREATMENT OF LUPUS ERYTHEMATOSUS,

was read by Dr. Stelwagon. Dr. Duhring had used this lotion with marked benefit in the inflammatory superficial forms of the disease, either discreet or confluent patches, whether recent or of longer duration. He did not claim for the remedy any specific power over the disease, but in several cases it was the only remedy tolerated by the skin. The following formula for the lotion was given:

R. Sulphate of zinc,
Sulphuret of potash.....āā grs. xxx.
Rose water..... ʒijss.
Alcohol..... ʒ iij.

M.

If this strength agrees with the skin, the quantity of the two active ingredients may be increased. The application may be repeated twice or more times in twenty-four hours, the skin being cleansed each time with soap.

DR. PIFFARD was astonished to hear that so many remedies had been employed in the treatment of a case of lupus, because it seemed so well settled that, in order to get rid of lupus, it must be destroyed. The methods of destroying it, which, in the majority of cases, act most successfully, are first, the use of the curette followed by cauterization, frequently the actual; and second, scarification. Doubtless the lotion would benefit certain cases, but he was unable to understand how it could effect a cure.

DR. ALEXANDER had, at present, a case under treatment in which he had practised scarification three or four times, and the first operation was followed by the disappearance of one patch of the disease; but since then the only effect produced was to make the patches worse.

DR. VAN HARLINGEN said that he saw one of Dr. Duhring's cases, and certainly very marked improvement followed the use of the lotion.

Several of the members failed to see how the lotion could produce much effect on such a disease as lupus.

DR. FOX, of New York, had secured his best results in the treatment of this disease by the local application of pure carbolic acid. Paint it over the part at intervals of a week or ten days, perhaps more frequently. In three cases he had succeeded in effecting a complete cure of the disease. The frequency of the application will depend on the rapidity with which the skin peels off and leaves a smooth surface ready for another application. He had not found that it aggravates the disease at all. He had also obtained beneficial results by the internal use of phosphorus, and thought that, perhaps, a judicious use of both remedies might secure still better results than had yet been obtained by either alone.

DR. STELWAGON said that scarification aggravated the disease in Dr. Duhring's cases; that pure carbolic acid was applied without effect; and that they were benefited

by this lotion only, which was applicable chiefly to the superficial variety of the disease.

DR. PIFFARD said that the dermatitis referred to by Dr. Stelwagon and Dr. Alexander after scarification, occurred as a matter of necessity, but that it did no harm. Scarification should be performed with great thoroughness, and the dermatitis which follows is of great advantage. It is substantially the treatment recommended by Hardee, namely, to excite a sufficient amount of new inflammation to strangle new lupus cells.

DR. HARDAWAY believed strongly in scarification and multiple puncture. He had treated one case successfully, however, by electrolysis.

A paper by DR. DUHRING, of Philadelphia, entitled, REPORT OF A CASE OF AINUM WITH MICROSCOPIC EXAMINATION,

was read by Dr. Stelwagon. The case was one which came under the observation of Dr. George B. Weston, of West Virginia, and to him Dr. Duhring was indebted for the specimen with the notes. Only a few cases of this disease had been reported in this country, and with reference to them the conclusion had been reached that it was caused by the application of a ligature. The patient was a negro, and the specimen consisted of one of the toes. The microscopic examination was made by Dr. Henry Wile, of Philadelphia, who examined it with great care, and reached the conclusion that the principal changes which existed were those that indicated general inflammatory condition.

DR. SHERWELL had treated many patients coming from Jamaica, San Domingo, but especially from Turk's Island, and had made inquiry concerning this affection, and had been led to the conclusion that it is due to traumatism from the application of a ligature around the toe; lazy negroes apply a ligature, and become subject to what is known as "ring-toe."

DR. HARDAWAY, of St. Louis, read a paper in which he described

A PECULIAR PAPILLARY ERUPTION.

It occurred in an otherwise healthy developed brunette upon the left cheek and both hands, and had existed at least a year, but gave no special inconvenience. The size of the papules varied from that of a grain of wheat to that of a split pea, and they were non-pedunculated. The eruption was discreet, of a dull lemon color, and of pellucid appearance. The papules were solid to the touch, gave the appearance of having liquid contents, but nothing could be obtained by puncture, and nothing could be squeezed from the papules. The eruption disappeared under treatment, without leaving any trace whatever. He had had five cases. The treatment for the most part had consisted in the use of a tar and mercurial ointment. All the cases were chronic. There was no evidence whatever that it was contagious.

Such an eruption as described by Dr. Hardaway had not been seen by any of the members of the Association.

LYMPHANGIOMA CUTIS WITH DERMATOLYSIS.

DR. J. E. GRAHAM, of Toronto, reported a case illustrated with photographs. Mrs. L—, twenty-one years of age. When five years old a tumor appeared in front of the elbow, which gradually extended upward and downward. The history from that time had been one of constant increase, and the growth had increased very rapidly during the past year. Its presence had not produced inconvenience. On the anterior surface of the arm the integument hangs down in bag-like pouches, which changes in color as the arm hangs or is raised. The papillary layer of the corium is hypertrophied, and the skin presents deep furrows. There is brown pigmentation near the elbow, and a few black hairs exist on the surface. The entire growth has a peculiar velvety feel. There is thickening of the skin, but no induration whatever. At the middle of the forearm there is a small tumor, which feels like a mass of blood-vessels beneath the

skin. The arm can be made smaller by pressure, and especially the small tumors, of which there are two or three. The tumors are not painful. The affected arm is almost as strong as the other. It is possible that the small tumor first seen existed at birth, but had been unrecognized. Dilatation of the lymph-channels was the probable pathological lesion.

Dr. Fox had seen one case which would bear comparison with Dr. Graham's.

Dr. ATKINSON had seen one case which was almost identical with that reported by Dr. Graham, except that the growth was situated higher up upon the arm. He thought there was dilatation with new growth of the channels, and regarded such a case as affording striking proof of the inaccuracy of the view put forward by Dr. Formad concerning the nature of tubercle, as we do not get tubercular inflammation in these cases, where it is well known that the lymph-channels are obstructed.

Dr. PIFFARD thought it practicable to remove the growth in sections by the use of the galvano-caustic ligature.

Dr. ATKINSON thought the probable cause of the disease would remain, and that removal of the growth would be followed by a return of the affection.

Dr. SHERWELL referred to a case of general lymphangioma.

The Association then adjourned, to meet at 9.30 A.M. on Friday.

FRIDAY, AUGUST 31ST—THIRD DAY.

The Association was called to order at 9.30 A.M. by the President.

The first order of business was the induction of newly elected officers. Dr. R. W. TAYLOR, of New York, who had been re-elected President, thanked the Association for the continued honor in electing him as the presiding officer for the ensuing year, spoke of the prosperity of the Society, and the amount of good work which it had performed.

The newly-elected Vice-Presidents were Dr. Arthur Van Harlingen, of Philadelphia, and Dr. J. E. Graham, of Toronto; Secretary, Dr. W. T. Alexander, of New York; Treasurer (re-elected), Dr. George H. Rohe, of Baltimore.

The remainder of the session was devoted to the examination of microscopic sections, prepared by Dr. Henry Wile, of Philadelphia, which accompanied Dr. Duhring's paper on "Ainhum," and also illustrated Paget's disease or malignant papillary dermatitis.

The Association then adjourned to meet at West Point on the last Wednesday in August, 1884.

Navy News.

Official List of Changes in the Medical Corps of the Navy for the week ending September 1, 1883.

WALTON, T. C., Surgeon. Detached from the Powhatan, and ordered to the Naval Academy, Annapolis, Md.

SIMON, W. J., Surgeon. Detached from the U. S. S. Constellation, and placed on waiting orders after completing temporary duty as member of a Board at Annapolis, Md.

McCLURG, W. A., Passed Assistant Surgeon. Detached from the U. S. S. Dale, and ordered to the Naval Academy.

DIEHL, OLIVER, Assistant Surgeon. Detached from the U. S. S. Constellation, and ordered to the Naval Academy.

JONES, M. D., Passed Assistant Surgeon. Ordered to temporary duty at the Naval Hospital, Washington, D. C.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending September 4, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
August 28, 1883.....	1	63	45	2	22	28	0	0
September 4, 1883.....	0	67	32	8	19	27	0	0
<i>Deaths.</i>								
August 28, 1883.....	0	17	8	1	8	14	0	0
September 4, 1883.....	1	24	2	8	1	21	0	0

CHLOROFORM NARCOSIS DURING SLEEP.—The evidence regarding this point is still accumulating. Dr. W. E. Ground, of Toledo, O., sends us a report of two cases in which he produced anæsthesia during sleep. One was in a child eighteen months old, the operation being that of the removal of a pebble from the ear; the other was in a child at the breast. The latter was apparently experimental in character.

THE BRITISH CHOLERA DOCTORS.—The twelve medical men who have been selected for service in Egypt in the cholera districts by the Foreign Office, with the advice and assistance of Sir Joseph Fayrer, will, on arrival, report themselves to Surgeon-General Hunter, M.D., and place themselves under his orders. They will be paid at the rate of £100 per month, with travelling expenses.

FLY-PAPERS.—In Prussia the sale of poisonous and arsenical fly-papers is only permitted to chemists and those who are authorized to deal in poisons. Such persons even are only permitted to sell them under the same regulations as must be observed in the sale of all poisons. These regulations require that a poison certificate be given with them, and also that the word "poisonous" be stamped on them.

A DRUGGIST SENTENCED.—Lacombe, the French wholesale druggist who was accused of fraudulently substituting sulphate of cinchonidine for sulphate of quinine, which he supplied to the Paris hospitals last autumn, has been sentenced to a year's imprisonment and fifty francs penalty, and is also called upon to pay for the advertisement of the judgment in a dozen French journals.

GRINDELIA ROBUSTA FOR ASTHMA.—Dr. Bombelon (Bergen on Rügen) recommends the smoking of cigarettes, the tobacco of which has been saturated with the resin of grindelia robusta, to asthma patients, whether they are smokers or not. The tobacco must also be well impregnated with saltpetre, which will facilitate its combustion and the development of smoke. If the patient is unable to smoke himself, the fumes are blown toward him.—*Zeitschr. d. Allg. öster. Apotheker Vereins. Ther. Gazette.*

ANOTHER MEDICAL COLLEGE.—The University of Niagara is about to start a medical department. The course of study is to be four years, and each course of lectures will continue for six months. The studies will be graded, and satisfactory examinations must be passed by the student before proceeding to a higher class. The examinations are to be conducted by a board of five medical men unconnected with the faculty of the department, to be appointed yearly by the trustees. The new college will be located at Buffalo, and the lectures will be delivered temporarily at the Hospital of the Sisters of Charity until a suitable building can be erected. The first session will begin on October 10th.

NERVOUS INDIGESTION.

By J. MILNER FOTHERGILL, M.D.,

LONDON, ENGLAND,

ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, PA.

SOME relations of indigestion connected with the nervous system may now be discussed. First, it may be well to consider reflex indigestion.

Reflex indigestion is a malady of women, for it is in women we see reflex disturbances best exemplified. We know that nausea and vomiting are the outcomes of a vesical calculus, or a pregnant uterus in the early months, or of a blow upon the testes. So ovarian irritation will often set up gastric symptoms, usually taken for primary indigestion. The ovary may be swollen and tender, or it may be fixed near the pubic brim by adhesions. When in front there is pain on emptying the bladder; when on the side, especially the left side, there is pain on emptying the bowels. From this centre may radiate disturbances of many parts. The extreme frequency of reflex dyspepsia from a tender ovary on the one hand, and the great neglect of the condition in medical literature on the other, must be my explanation for going into this subject somewhat fully.

The patient is usually a comparatively young woman with pallor in her features and general anæmia; but by no means necessarily so. Her complaint is of indigestion coming on soon after taking food, often with nausea and loss of appetite, less frequently with actual vomiting. Yet the tongue is clean; sometimes it has a slight coating; rarely is there any rawness or approach to the bare tongue of gastric irritability. The tongue puts the experienced observer on his guard. Pressure is made over the region of the ovaries, and when it is made over the tender ovary pain is produced—a sickening pain, giving a feeling of faintness, and reflected in the patient's features. Usually she asks to sit down. In a well-marked case the following symptoms, sometimes a few only but often all, are manifested, much depending upon the patient's intelligence and readiness to answer: First, then, if there be pain produced on defecation, there will be reflex constipation, the pain inhibiting the vermicular action of the bowel. Then there will be found "pain under the heart" as women term it. This is intercostal neuralgia with the three tender spots of Valleix, one at the left apex, a second at the outer edge of the left scapula, about the middle, and a third at the foramen of the posterior rootlet of the nerve, usually the sixth.

I have written elsewhere "waves of nerve-perturbation may arise in an ovary and traverse a series of nerve-fibrils until they reach the peripheral endings of an intercostal nerve, where they are felt as gusts of neuralgic pain." Further experience merely strengthens this view. There will usually, too, be that pain and weight at the vertex with depression or lowness of spirits, and tendency to cry, the outward indications of cerebral anæmia of the posterior lobes, found with irritation in the lower bowel and the generative organs. Then there is anorexia, indigestion, and in some cases vomiting. Such is the real pathology of those cases of so-called subacute gastritis in young females, where obstinate vomiting goes on for weeks, resisting all treatment of the stomach, scoffing at bismuth, hydrocyanic acid, oxalate of cerium, and

all remedies of value in morbid conditions of the stomach; where the patient is greatly reduced, the friends almost distracted, and the physician worried out of his life. Yet a year or two afterward, on asking after the object of all this anxiety, it is found she is well and probably married. This vomiting may have gone on for a considerable time and been interpreted as gastric catarrh, or gastric ulcer, and treated as such—without satisfactory results. Then there is also some pelvic matters which clinch the diagnosis. The uterus is reflexly filled with blood, is turgid and vascular, and consequently there is menorrhagia with leucorrhœa. Orgasm is readily produced by slight friction, or occurs spontaneously in sleep; and this irritability communicates itself to the adjacent bladder-centres in the cord, and there is inability to retain the contents of the bladder. Further, there are commonly times of great itching with heat or dryness in the fundament, and often in the vagina also.

Such are the features of a well-marked malady, which, however, has not yet found its way into our text-books. Word by word, indeed letter by letter, I learned to spell it out among my hospital out-patients; but the trouble brought with it its reward in the power to detect, and consequently to treat correctly, a very common malady, little influenced by measures directed at one or other of the outcomes of the condition, yet often tractable to appropriate measures. Those who have taken the pains to master the malady in all its details testify to the advantage they gained in practice therefrom. It is a condition commonly unsuspected. It frequently lies at the bottom of the ill-health which, when coexistent with an old apex consolidation, is taken for commencing phthisis; and when profuse night-sweats are added to the effects of the indigestion, the weakened lung-apex may and often does break down. How often this misinterpretation has wrecked the peace of a family, it becomes not me to say. I am concerned more with the matter of my own familiarity with morbid conditions than other men's shortcomings. But since the malady has been clear to me I at least have been able to avoid mistakes which, previous to that date, occurred with myself in common with others; and it is in consequence of my experience, past and recent, that I urge so strongly upon my readers the desirability of grasping this well-marked, if often unrecognized malady.

The sex, and often, too, the age of the patient, should put the physician on his guard. If the tongue also be normal or only slightly coated, and free from the appearances associated with gastric irritation; then the examination of the patient ought to be conducted on the lines just laid down. It travels over some very delicate ground for both physician and patient; and therefore must be conducted with every consideration for the patient's feelings. Yet enough can be gleaned from the most difficult patient to cross-examine, usually at least to determine the nature of the case. Sometimes it is possible to state her case to her, including her most inward feelings in a manner which makes the patient feel as if in the presence of a magician.

Having made the diagnosis, the treatment suggests itself. A blister over the tender, or otherwise offending ovary. Bromide of potassium, the drug *par excellence* in all reflex affections, and sulphate of soda or magnesia for the constipation. If there be also night-sweats then some atropine, say from a seventy-fifth to a twenty-fifth grain at bedtime. Then if there be much sickness it may be well to

give some bismuth, with or without hydrocyanic acid and soda, but this is only ancillary to the other treatment. Usually some injections of alum water are required for the leucorrhœa. A rational treatment indeed, founded on the nature of the malady, and, presto, the intractable patient gets well, to the unfeigned delight of all. Sometimes the result is not so satisfactory as to time, while in those cases where the morbid ovary is bound down by adhesions, relief is all that is practically attainable. But the bulk of cases readily do well, with gratitude on the part of the patient, and with credit to the physician.

Now some other matters may be mentioned. First comes the effects of mental strain and worry upon the digestive organs; second, the effects of mal-products of digestion upon the brain; and lastly the combination of the two.

On this wide subject general remarks are all that are possible, as the individual necessities of each case have to be and must be studied, for successful treatment, and what these are only becomes visible when the case presents itself before the physician. Those seeking further information will find it in my work on "Indigestion and Bilioinsness."

First as to the effects of carking care upon the assimilative organs, they have been recognized by writers, medical and other, since the dawn of literature. "Lean, hungry men" have been regarded as the type of the brain-worker, including the conspirator. While the rubicund visage of the well-fed man has ever been looked upon as indicative of an easy mind. Such generalizations are broad and true; but the subject admits of closer handling in the light of the present day.

In "this madly striving age" the pressure of business absorbs so much of the daily store of energy that the digestive organs are robbed of much of the *vis nervosa* that belongs to them, and, therefore, are only capable of digesting light food. Of old when anything uncommon had to be done, a good foundation was laid, as matrifamilias expressed it, by a substantial breakfast; something in excess of the wonted fare. Whether such practice is successful in the present day is a matter for question. Probably the experiment is rarely tried among others than Yakoots or Indians. Then when the work was over an extra bountiful fare was provided, the huntsman's supper. This was all very well for men who were out in the open air, in the chase or war; but it is not a safe practice at the present time, except with those whose digestive organs are unimpaired, and retain much of their primitive Anglo-Saxon capacities.

The rule of the present day is rather in the opposite direction, viz., to have a very light meal after any special demand upon the system, possibly with some alcohol, though on this last the right of private judgment is brought to bear more than on any other matter connected with health. A few illustrations will demonstrate what it is desired to convey. One of our leaders of scientific medicine, one of the least fanciful of men, commonly lunched on a beefsteak, eating and enjoying the fat. But experience taught him that whenever more wearied than usual it was prudent to leave the steak-fat and take butter instead. When tired he could not digest the beef-fat, which he enjoyed as a rule. A lady well known to the writer has always to be very careful about what she takes when tired, else a severe attack of indigestion will be experienced. After a long walk, or its equivalent, a light meal alone is permissible, or compatible with comfort, and one of McKesson & Robbins' pepsin pills is in request. Some fried fish after a long walk set up severe dyspepsia with delirium, and left behind great susceptibility in the digestive organs for months after, requiring the greatest care in diet, and a medicinal course for its removal.

An American lady presented herself one day with confirmed dyspepsia, dating definitely from a certain long, tiresome drive, followed by a table d'hôte dinner at Genoa, which, being hungry, she enjoyed. She was quite of my way of thinking when my views were laid before

her. Frequently cases come under notice where tiring evening work, as a Sunday evening service, is met by an unusually good supper—the house-wife's treatment. This may have been all very well in the days of yore, but it certainly is not well at the present time. A light meal and a little wine, as Timothy has wisely counselled, are the proper method of meeting the emergency in our day. What can be digested without drawback under ordinary circumstances will not be satisfactorily digested when the system is exhausted either by bodily or mental toil.

The effects of acute emotion in upsetting the digestion are thoroughly recognized; in fact, anorexia is so set up, and the food which would not be digested is not taken. But we are still far from comprehending fully the more chronic effects of wearing care or anxiety. Yet the fact must be recognized that where the mind is greatly exercised, while the body is insufficiently exercised, the dietary must be regulated accordingly. A plate of porridge, oatmeal, cerealine, or hominy, with a pint of cream, and some stewed fruit to finish off with for breakfast. For lunch, some well-buttered mashed potatoes, with biscuit and butter and a glass or two of milk. For dinner some boiled fish, followed by some chicken or game, and a milk-pudding made without an egg, and digestive biscuits and butter (with just a nip of cheese as a flavoring agent for those who can eat cheese), with a glass or two of good French wine or its equivalent. Such is the dietary, or ought to be, of the man who has much brain-work to do. And further, he should allow himself plenty of time over his meals. It is bad economy to save time by cutting it off the meal-time. And such is the dietary that must be enforced when the brain-worker has made himself a patient. The use of pepsin to aid the natural digestion was given in the first article and need not be referred to again (see THE MEDICAL RECORD, September 1, p. 225). Then there should be a sufficiency of sleep to rest the wearied organism. A day of work followed by another day of play in every twenty-four hours, is the order of the present day, and to secure this the time for meals is cut down to a minimum, and the hours of sleep curtailed to an injurious extent. But the experiment will be found a failure; it is not among the potentialities. The busy brain-worker must learn to see that he cannot tax his system at will; if he will not be told he will be made to comprehend the subject. And he may depend upon it—whether these remarks are acceptable or not—it is much better to take care in time than to do the mischief and have to take the care when partly disabled. My counsel to such patients is as follows: "You had better adopt the habits of an invalid in order that you may not become one. You had better take care before you break down than wait till you break down and are compelled to take care of yourself with your working-power crippled!"

The preventive treatment of neurosal indigestion is quite as important as its palliative treatment when once established. The lines are the same in both, viz., to give easily assimilable food, rich in fat, and containing albuminoids, but in sparing quantities; to allow a proper time for meals, and a sufficiency of sleep. Beyond this there is the matter of phosphorus. Phosphorus and fat in combination are the food of the brain par excellence; and to this dietary, rich in fat, it may be well to add phosphorus in pill, or better still in the syrup of the hypophosphites. Yet when all this has been done, and the latest revelations of physiology worked out by the chemist are placed at the patient's service by his physician, there comes that indispensable factor which the patient alone can do, viz., take proper care of himself. When I look round on the men I know, whether in the profession or out of it, which are those who are steadily holding their own, accomplishing huge quantities of work, yet with their energies unimpaired and their working power as good as ever? They are those who do not add a day's play to a hard day's work! Men who, after a hard day of work, take their dinner quietly and

slowly—not bolting it to rush off to the theatre or other place of amusement, as a billiard-table, perhaps. Who spend a quiet evening in intellectual pleasure, unbending the bow, while adding to their stores of knowledge: and going to bed early, to sleep in a cool bedroom, instead of breathing a hot, vitiated atmosphere till nearly midnight, gulping down some indigestible mass like a lobster salad, and then, quite late, lying down to sleep—to leave a wearied system to digest the late supper.

This is an aspect of nervous indigestion which is worth pondering over. The physician can first digest the matter himself and then expound it to his patients. There is another matter, too, which needs more general recognition.

Of old, as said before, the more work the more meat. "Work goes in at the mouth." The fact that an underfed animal, man or beast, could not accomplish much work was vividly realized: and the hard-headed northern farmer had his farm laborers eat at his own table. But the converse is not so absolutely certain. Meat will not necessarily give strength, *i.e.*, if it be not digested. Constantly patients—not with primary indigestion, for that pretty well regulates matters itself—suffering from malassimilation come under notice, who have been eating all the animal food they can get down, under the impression that this is the plan to adopt. Probably, if a married man, his wife has been aiding and abetting him in his pernicious efforts to acquire strength. They have studied the advertising columns of the newspapers, and read of "Iron and Quinine Wine" (an admirable tonic in mere asthenia or debility), and have added that to the meat dietary; and yet the patient grows visibly weaker and feebler under the regimen. When the liver is not working well nothing will further derange it more certainly than a chalybeate.

In these cases the albuminoids which reach the liver by the portal vein are not elaborated and passed forward as the serum albumen of the liquor sanguinis, but are thrust downward as bile acids or lithates. "To feed the patient is to feed the disease," as the old phrase ran. To crowd the liver with albuminoids by a meat-dietary, the natural digestive powers being helped by artificial digestive agents, is still further to embarrass it. The attempt defeats itself. The mal-products of assimilation find their way into the blood and act as toxic agents, enfeebling the mental processes, involving the mind in gloom, and depriving the unhappy individual of all pleasure in life, till death becomes positively attractive. Such are the untoward outcomes of the delusive attempt to gain or rather to regain strength of mind and body by a highly nitrogenized dietary. Yet the proper treatment of such a case is met by prejudice, by preconceived opinions. Your wisely regulated dietary is described as "starving the patient!" You strive to sweep out the nitrogenized waste by a mercurial followed by some sulphate of soda; this is "too reducing!" You are liable to be scoffed at as an antiquated quack-salver, who has no right to exist outside of a museum for antiquities. How many women do I know now wearing widow's weeds, who might still have had husbands and bread-winners had not the present murderous age of stuffing overmastered prudence, and the lessons of physiology and clinical medicine been set at naught!

Whether such regimen is old-fashioned or in advance of the times, matters little. It will have to be adopted. The capacities of the liver will have to be appraised; and if Dame Nature, knowing better than we perhaps do, attempts to balance matters by cutting down the appetite, it is not well to thwart her by bitters. If a man feels unequal to his work, it may be wise at times to cut his coat according to his cloth. It may not always be prudent for a man to whip himself up to an ideal of energy and working-power, as if he was a steam-engine. The increase of Bright's disease in our day may not be entirely accounted for by our increased acquaintance with it and the means of its detection. Over-work, if

Clifford Allbutt is to be believed, and overcramping with meat, if some others of equal authority are to be credited, have much to do in upsetting the liver first and damaging the kidneys afterward, to say nothing of the lithiasis, cholæmia and toxic oxalates which belong to this condition of secondary indigestion, while the relations of glycosuria to over-taxation of the nervous system are now well recognized. This may be an unacceptable doctrine, but it is to be feared it is true and well-founded.

AN OPERATION FOR THE REMOVAL OF THE THYROID GLAND IN PARTS.

By WILLIAM FULLER, M.D.,

GRAND RAPIDS, MICH.

THE attention of the physician is frequently called to thyroid enlargements, not only on account of the deformity occasioned by them, but by the troublesome and even dangerous inconveniences which are developed in some cases. Simple hypertrophy involving the entire gland and of moderate dimensions commonly subsides by regulating the general system, the administration of iodine in some form together with local counter-irritation over the swelling by means of tr. iodine co. or ung. hydrarg. biniodidi.

In other cases, presenting partial enlargements which project as tumors on the side or in the middle of the neck, and in some cases in which the entire gland is enlarged, the above remedies are inadequate. The tumors are either large cysts or composed of a collection of a great number of minute sacs from the size of a flaxseed to a pea and containing fluids of various color and consistency. Internal medication and counter-irritation has no appreciable effect upon them. Puncture of the sacs and drawing off the fluid is only temporary and may be done for information as to the nature of the case. Galvanism applied to the skin is of no benefit, but by means of needles introduced into the tumor I have succeeded in diminishing and softening it up somewhat. I generally use a small trocar canula in order to allow of the escape of gases formed by electrolysis, and from four to twelve cells of the Galvano-Faradic Company's battery. A small abscess formed in a few instances, which was of no moment, as the pus found exit through the puncture or was evacuated by the knife. I have practised the injection, by the hypodermic syringe, of tr. iodine co. in a number of cases, and by its persistent use attained some success, but not what I had hoped for from favorable reports that I have read. In one case, in which the enlargement was great, I injected from fifteen to thirty drops of tr. iodine every week for three months at a time, desisting for a short time only when symptoms of iodism were developed. I continued this treatment with few intervals for about two years, when it was interrupted by the woman becoming pregnant. I also tied the superior thyroid arteries in this case, which immediately softened and reduced the swelling to some extent. The size increased during the pregnant state, as it had done on previous occasions. It is now about one-half its former size and remains stationary. I have seen injections of tr. iodine, practised a number of times upon thyroid enlargements in horses, effect a cure in every instance. The method was to puncture the gland deeply with a penknife and to force into it, with a metallic syringe, from one to two ounces of the simple tincture at once. The result was swelling, sloughing of the gland substance, suppuration, and recovery in about two weeks with little or no scar. I should be afraid to try this in the human subject on account of the situation and important relations of the tumor.

I injected ergotine on one occasion, the effect was immediate, the patient turned very pale, fell down, became cyanosed, respiration gasping, and he regained consciousness slowly and with difficulty. I think that I used a solution of three grains and injected slowly.

Cysts evacuated by the trocar soon refill, and in my experience injections into them are of little use, but I have succeeded in removing them by free incision into the sac and the use of means to excite suppuration. I have found this process to be tedious and troublesome and will relate two cases in illustration of the results obtained.

A young man, aged eighteen years, much debilitated, and having a pale cachectic appearance, had a swelling just above the upper end of the sternum, which seriously interfered with respiration and obstructed the passage of food. I punctured it with a trocar and drew off about half a pint of pale reddish fluid, made an incision into the sac at once, and though not aware of dividing a vein, I was surprised by a rather profuse flow of venous blood, which I think came from the rupture of small vessels lining the sac. However, the hemorrhage was immediately checked by the introduction of a sponge saturated with strong liq. ferri perchlor. The sac was quite large and the finger could be passed freely behind the upper end of the sternum and the clavicular articulations, and laterally under the sterno-mastoid muscles. Its relations could be easily distinguished, viz., the innominate and carotid arteries, trachea, and œsophagus. Some swelling and fever were present on the following day; the sponge was removed and the sac washed out, twenty grains of quinine were administered, and the neck was enveloped with cloths wet in a solution of ammonia chlor. The swelling and fever subsided, and suppuration was established in a few days. A large-sized drainage-tube was inserted and the sac was frequently cleansed with the solution of ammonia chlor. The sac contracted and discharged a sero-pus for about two months. Smaller drainage-tubes were substituted and, lastly, the opening was allowed to heal up, as the discharge became reduced to a very small quantity. After a lapse of a few weeks the swelling and tenderness returned, a yellow and fetid pus was discharged, and drainage was again resorted to, with injections of tr. iodine, saturated solution of iodoform in ether, a saturated solution of zinc chlor., and many other remedies at various times, with the view of establishing a healthy action or destroying the secreting surface, but without avail. Finally, when I had almost despaired of closing the troublesome tract, it became infested with maggots. I let them alone for a few days, since their presence did not appear to trouble him and then cleared them out with a strong solution of plumbi acet. The tract healed up at once, has remained so for over two years, and the young man enjoys robust health. Just what function maggots may be designed to serve in the economy of nature, I will leave it to the reader to form his own opinion, but I would suggest that by devouring sloughs and flesh endowed with little vitality, they serve to cleanse the wounds of animals, and by crawling into deeper parts they form channels for the discharge of fluids and thus become an important factor in Nature's system of providing for the healing of wounds by drainage and cleanliness, the principles upon which the success of the surgical art depends. I once saw a case in a horse turned to pasture on account of two large callous tumors on his shoulders. They were eaten out clean by maggots and scarcely a scar was left to mark their situation.

The second case was a girl aged twelve years, pale, sallow, and debilitated. Breathing was difficult upon the slightest extra exertion in walking or in going up stairs, and she was affected with occasional attacks of spasmodic croup. There was a swelling at the root of the neck since she was a year old, having the appearance of a large goitre. Upon puncture it proved to be an abscess, and was drained; but, contrary to my advice, a small drainage-tube was inserted. During two weeks she suffered from a high fever, which partially subsided when the discharge became more free. She was highly nervous and afraid of surgical instruments, and the case coming under my immediate care, I introduced a seatangle

into the small opening, and after distending it inserted a large tube. All febrile action presently subsided, the appetite improved, and she gained rapidly in her general health. Her breathing improved and she was allowed to play in the open air with other children, which her former condition prohibited. I applied many things to the cavity of the sac with the view of irritating and destroying the secreting surface, such as tr. iodine co., cantharides, ung. hydrarg. biniodidi, argenti nit., pure nitric acid, iodoform, saturated solution of zinc chlor. in alcohol, solid zinc chlor., actual cautery, and other things too numerous to mention. The sac was rebellious to all treatment, recovering its former condition after each application. Finally I introduced a gold drainage-tube five-eighths of an inch in diameter, so as to expose the whole surface freely to the air and for cleanliness. The secretion was very much diminished in a short time, and in the course of a few months the sac became healed to the integument around the tube, which was then removed. The present condition is an opening about half an inch in diameter leading into the sac, which is contracted into an irregular cavity about the size of a walnut and lined with a membrane resembling the mucous membrane of the larynx, with which, however, it does not communicate. She has, since the sac was freely discharged, developed from a stunted and puny girl into a robust young woman. It is about two years since the sac was opened, and from the experience that I have had of these cases I conclude that the treatment of them is very tedious and dangerous, unless very free drainage is maintained.

I have removed solid tumors of the thyroid gland four times. In the first case I removed the tumor with its sheath, successively tying all its attachments before dividing them as the dissection proceeded. The operation was comparatively bloodless, but tedious, so that the patient was a long time under chloroform. The wound was not approximated until suppuration was established, and an uninterrupted recovery took place, leaving only a linear scar. This case has been reported in the *Detroit Lancet*, December, 1878.

Upon a study of the blood-supply to the thyroid gland it will be observed that the larger vessels rest upon the sheath of the gland and run within the processes which separate its lobes. The superior thyroids are distributed upon the surface and the inferior arteries enter the processes near the trachea, along which they are distributed, and also to the posterior surface. The gland substance is supplied by numerous small vessels which pierce the sheath in the course of the larger vessels; consequently, if an incision is made through the sheath and the gland is separated from the inner surface of its capsule, no large vessel is divided and very little hemorrhage is encountered. If the finger is passed around a lobe which is left *in situ* there is little or no bleeding, since the hemorrhage is restrained by the pressure of the surrounding tissues. After a time a ligature can be tied around the base of the lobe and it may be removed by the knife, or without a ligature the lobe may be broken off and a piece of sponge saturated with strong ferri perchlor. can be pressed against the stump, which will effectually restrain the blood. There is no advantage gained by injecting iron into the substance of a lobe before removal. A portion of the gland, or the whole of it, may be removed at a time in this manner with comparatively little loss of blood, and the operation is attended by little pain and shock.

One assistant only is required, which, however, is not necessary, and the operation is robbed of its formidable aspect. I have operated in this way upon three patients, two of them died from other causes than any incident to the method employed for the removal of the tumor. A ship carpenter, aged thirty-five years, had an enormous goitre, the circumference of the neck measuring 27½ inches. The tumor projected beyond the chin, which rested upon its upper surface, it covered the upper part

of the sternum and the clavicles as far as the shoulders, large veins coursed over its whole surface, and especially in front. There were two large perpendicular trunks about the size of the thumb running parallel about two inches apart and united in the centre by a transverse trunk of the same size so as to form a letter H. There was a strong bruit heard all over the tumor, the neck and head were much congested and bluish, the eyeballs prominent, and he wore an expression of great anxiety. His voice was crowing and he had frequent attacks of spasm of the glottis. Expiration and inspiration both were prolonged and difficult as well as deglutition. There were bronchial râles over both lungs. This growth had steadily increased, notwithstanding that he had used many remedies, external and internal, by the advice of many physicians. His case was indeed desperate, and apparently beyond hope. He implored assistance at any risk, desirous of submitting to an operation, though informed that he would more than likely die before it was completed. Under these circumstances his urgent request could not be refused and I determined to operate, which I did with the assistance of several medical gentlemen of this city. Chloroform was not administered, nor were the tissues very sensitive on account of the stretching of the nerves. A curved needle was passed under the large transverse vein crossing the neck, and ligatures were applied on each side of the median line. An incision was made under the chin about two inches long in the middle line and another below near the sternum, their depth extending through the capsule of the gland. These were quickly made as the bleeding was profuse, and the fingers were thrust from above and below until they met along the trachea behind the mass. Two buckskin ligatures of large size were passed through the channel made by the fingers and were tied over the mass on either side as far apart as possible, and stitched to the integument to prevent them from slipping. Buckskin was used because I thought that it would be less liable than hard cords to cut into the friable tissue of the tumor, besides it possesses a certain amount of elasticity. The incisions above and below were now connected and the trachea exposed. The hemorrhage at this stage was small in amount, partly due to the faintness of the patient. The gland substance protruded through the wound, a large portion was removed and I was surprised to find that as the pressure was relieved in front of the trachea the respiration became more difficult. This tube was flattened by lateral pressure and not crushed back against the spinal column as I supposed. The patient was much exhausted, consequently I opened the trachea and introduced a rubber tube of half an inch calibre and six inches long, of sufficient length to reach between the trachea and the integument, and through which he breathed easily. He sat in a chair leaning back during the operation, and sustained himself with great fortitude. He was put into bed and a sponge wet in warm water was placed over the end of the tube. He passed a very comfortable night, breathing and sleeping quietly, his countenance looked pleasant in the morning, there was no fever, and his appetite was good for tea, toast, and an egg for breakfast. The ligatures were loosened, and as there was no bleeding they were removed. I found that the gland was easily separated from its sheath with very little hemorrhage and pain. I loosened a lobe in this manner, broke off its attachment near the trachea, and a piece of sponge saturated with liq. ferri perchlor. was applied to the stump. In two days the whole or nearly all of the tumor was removed, a lobe or two at a time, as the patient's feelings would permit. The cavity was kept clean by frequent washing with a weak solution of ammonia chlor. Subsequently his spirits and appetite continued good, he partook freely of beef-tea, eggs, whiskey sling, etc. His temperature ranged from 101° to 103°, tongue was clean and moist, and the bowels moved occasionally without medicine. This happy state of affairs continued up to the tenth day after the operation, when

the neck had contracted nearly to its natural size, the sterno-mastoid muscles showing plainly, and the wound was granulating and secreting a healthy pus. At this juncture the night nurse unfortunately got drunk, and at 8 A.M. next morning I found my patient out on the floor in a cold room, with the tube displaced. He was almost strangulated and in a violent chill. He never recovered from this chill and the shock of fear. The wound immediately took on a dry appearance with no activity, and he gradually sank and died upon the sixteenth day after the operation. There was difficulty of swallowing two or three days before his death, food and drink coming out at the tracheal wound.

My next case was a lady of sixty-two years. She had a hard, immovable tumor, situated in the region of the thyroid gland, and was suffering from extreme dyspnoea, which had been steadily increasing upon her for some months. The tumor appeared to be of a cancerous nature, was firmly adherent to the larynx, and was about the size of a goose's egg. I made an incision into it about three inches long in the middle line of the neck. There was considerable hemorrhage, which was staunched by pressure and perchloride of iron, after which I removed a portion of the gland as in the above case. This was at 3 P.M., and the respiration was somewhat relieved, but at 1 A.M. it was so difficult that I was forced to perform tracheotomy, which was a very difficult operation under the circumstances, the trachea being flattened laterally and pushed out under the left sterno-mastoid muscle. It was found with difficulty by thrusting a small trocar in different directions through the tumor. I introduced a piece of rubber tubing, which was changed frequently and kept clean as in the previous case. She also died on the sixteenth day after the operation from exhaustion and congestion of the lungs, the course of her case being about the same as in the previous one.

One great difficulty encountered in these cases was the impossibility of preventing fetid gases and fluids from entering the trachea, although the greatest care was taken to obviate it. This was the reason that I refrained from opening the windpipe immediately in the last case. I think that this cause contributed largely to produce the unfavorable results.

The following case had a more successful termination: A horseshoer, aged about thirty-eight years, had an enlargement at the root of the neck, which had been increasing in size for three years, and for six months it interfered with his breathing, especially in stooping, so that he was obliged to relinquish his business. In July last, while walking on the street, he had an attack of vertigo, a sudden increase in the difficulty of respiration, and a sensible enlargement of the tumor. He came into my office in a state of great alarm; there was a strong pulsation of the carotid and apparently of the tumor, which simulated aneurism. It was about the size of the closed fist and situated on the left side extending from the clavicle to the upper border of the thyroid cartilage. I concluded that it was an effusion of blood within the thyroid sheath, and punctured it with a small trocar, drawing off about an ounce and a half of dark-colored blood, which relieved the tension and the difficulty of breathing. A cold compress and bandage were applied and he was given eleven drops fluid extract digitalis every two or three hours until the heart's action was quieted. He sent for me in about two weeks and stated that he had suffered from fever and chills for a week, and that his neck felt sore to the touch, with a throbbing in the tumor. There was a tympanitic note over the seat of puncture, and upon introducing the trocar again there escaped a fetid gas and bloody pus, which was evacuated freely by the knife. Introducing the finger, the lobes of the enlarged thyroid gland could be felt. These were separated from the capsule, broken off near the trachea and into small pieces, so that by squeezing the sac the débris was ejected through the opening. Small pieces of sponge with a string attached to each and saturated

with liq. ferri perchlor. were immediately introduced and checked the hemorrhage. The sponges were removed next morning, the cavity washed out with a solution of ammonia chlor., and a large drainage-tube introduced. The operation required no assistant and was done at once when the opportunity presented, without exciting the patient's mind by making him aware that any important operation was in progress. Cleanliness and free drainage constituted the treatment, with the exception of one twenty-grain dose of quinine. His fever subsided after the operation, and as he felt well no note was taken of his temperature. The cavity slowly contracted by granulation, and recovery was complete in about six weeks. There is a small nodule on the right side of the neck and a little thickening in front of the trachea, but the breathing is free and the tumor on the left side has entirely disappeared.

ON THE TREATMENT OF PALPITATIONS OF THE HEART.¹

By PROFESSOR GERMAIN SÉE,

MEMBER OF THE ACADEMY OF MEDICINE, MEMBER OF THE FACULTY OF MEDICINE, PHYSICIAN TO THE HOTEL DIEU, PARIS, FRANCE.

PALPITATIONS consist in an increase of the activity, though not of the energy of the heart.² From an etiological point of view they may be ranged under four heads: 1, Nervous palpitations; 2, Physico-dynamic palpitations; 3, Anæmic palpitations; 4, Toxic palpitations.

I shall treat of all these species of palpitations, but not exactly in the order given, and for convenience will begin with the last, which I have called

TOXIC PALPITATIONS.

The first care of the physician when he finds himself in presence of a patient who has, or fancies he has, real palpitations, should be to examine into the daily hygienic and dietetic habits of the patient. The abuse of tobacco, the immoderate use of tea, coffee, alcohol, may produce palpitations with or without arrhythmia, as well as intermissions. If, in order to obtain prompt abandonment of the abuse, it is generally sufficient to warn patients of the danger which menaces them, it is no less true that sometimes one meets stubborn resistance in the case of inveterate smokers and drinkers, to whom the vicious habit has become a passion and almost a necessity.

In these cases it is necessary to proceed by a gradual process of withdrawal, and especially where the prolonged use of tobacco has created a sort of habituation—a veritable accommodation in the organs and functions, which it would be dangerous suddenly to suppress. There are a great many smokers whose easy and healthful digestion depends on the cigar or pipe which they smoke after meals; others find the best remedy against constipation to be a pipe smoked on an empty stomach; others maintain that their brains will not work to advantage without the customary smoke. It is precisely these individuals who become subjects of palpitations, and if you would treat them successfully you must not too suddenly and completely wean them from tobacco. Better by far limit the quantity of tobacco than to impose on them absolute deprivation, which, moreover, it is very difficult to enforce. All that you need do, in order to obtain a

cessation of the palpitations, is to transform abuse into moderate use.

It is much easier to arrive at the suppression of the use of tea and coffee. It is more difficult to procure an abatement of alcoholic excesses, which, by the way, seldom and only for a brief period, manifest themselves by palpitations; they soon terminate in degeneration of the heart.

PHYSICO-DYNAMIC PALPITATIONS.

When, after an earnest inquiry, you have succeeded in eliminating from the group of probable causes the influence of poisons and of substances which trouble the action of the heart, the duty of the physician will be to investigate the state of the heart, its orifices, its valves, its proper texture, its lining membrane.

It is deserving of remark that it is precisely the larval affections, that is to say, those which do not produce any abnormal murmurs, as is the case with simple dilatation of the heart, which oftenest give rise to palpitations. In these cases digitalis finds its proper place; it tones up the debilitated heart and gives regularity to its beats.

DIGITALIS IN THE PALPITATIONS OF ORGANIC DISEASE.

When we are concerned with hypertrophies consecutive to valvular insufficiency or constriction of the orifices, there is a first question to answer before we can decide on the treatment. Is this hypertrophy sufficient or not to compensate for the obstacle to the outflow of blood in the case of constriction of the orifice? is it sufficient to enable the ventricle to clear itself, in the event of regurgitation from leakage of the valves? If so, that is to say, if the hypersarcosis is sufficient to enable the heart to fill the arteries, digitalis is useless, without being positively dangerous, unless by long continuance in its use.

Let us take an example: In Corrigan's disease (aortic insufficiency) the left ventricle constantly grows thicker and stronger by reason of the extra work imposed on it in propelling into the aorta the regurgitant blood, as well as that coming into its cavity from the auricle. As long as there is no venous stasis in the lungs, or œdema of the lower extremities, one may take it for granted that the hypernutrition of the ventricle is sufficient to overcome the disastrous effects of the reflux. Why then prescribe digitalis? Wait a while, the time will come, with almost absolute certainty, when, unhappily for the patient, the action of the heart will be troubled. There will be palpitations which will necessitate the use of digitalis, and in this case you are not to fear the effect of the drug, even if the heart's impulse suggests exaggerated energy; it is but the semblance of increase of energy. On the other hand, digitalis does not do harm when given for the hypertrophy itself. Heretofore it has been generally believed that hypertrophy may be excessive, and render one liable to danger from active congestion of the brain or lungs. This is a mistake, and it is as much as ever if the hypersarcosis is sufficiently pronounced to effectually overcome the obstacles to the outflow or regular progression of the blood. No one has ever seen active cerebral congestion result from exaggerated afflux of blood to the brain by reason of a hypertrophied heart. In the mechanical diseases of the heart you have not active but passive congestions, the heart having no longer sufficient contractile force to enable the blood to pass through the capillaries and veins. Therefore there is no absolute contra-indication in this disease to the administration of digitalis.

The indication for digitalis, however, becomes very plain if dyspnea or œdema comes on, showing that the heart is flagging in its work of blood-distribution. The same may be said of palpitations arising from hypertrophy in general. Suppose, for example, that you have a case of compensatory hypertrophy, accompanied with palpitations, in a nephritic patient (this would be a rare event, for arrhythmia would be the rule); you may without

¹ Translated, by permission of the Professor, for THE MEDICAL RECORD, by E. P. Hurd, M.D., Newburyport, Mass.

² [Professor Sée makes a distinction between the ataxic and the arrhythmic forms of heart disease, which he still further distinguishes from intermissions. Palpitations are ataxic manifestations, and are characterized by accelerated pulsations. Arrhythmia is disorder of rhythm, and the disturbance may pertain to the order, number, and duration of the pulsations. In the case of intermissions the normal and for the most part regular series of beating is from time to time and more or less periodically interrupted by a momentary arrest of the heart's action. If the pulsations are irregular, it is arrhythmia. If they appear to be more intense and rapid, we call them palpitations. In true intermission the heart's action may be more intense, we can hardly say, however, that there is deviation of rhythm; we notice only the pauses at the end of every 4, 5, and 6 pulsations. Bouilland calls these arrests or hesitations of the heart *false stops* faux pas. In practice these different kinds of abnormal functional working of the heart are often confounded, and it is true, as Professor Sée admits, that palpitations often coexist in the same patient with arrhythmia and intermission.]

hesitation prescribe digitalis. In spite of affirmations which have recently been made respecting the danger of these hypertrophies and the part which has been attributed to them in the production of uræmic cerebral accidents, digitalis does not augment the hypertrophy; the function of the hypertrophy is that of a moderator, and digitalis can in no way render harm.

There are certain palpitations due to hypertrophy where digitalis is of less utility. I refer to hypertrophies attending adolescence; sometimes these result from displacements of the heart by faulty chest-conformation. These hypertrophies are attended with palpitations; but it is also noteworthy that young men may suffer from palpitations from other causes, and that these palpitations may be about as troublesome and persistent as those which result from hypertrophy. Onanism is a fruitful source of such functional palpitations. As to the diagnosis, the hypertrophies I am speaking of may be known by augmentation of the volume of the heart, as shown by increased dullness, and displacement downward of the apex of the heart. These signs coexisting with palpitations would suggest that we have to deal with the hypersarcosis of adolescence; in other words, with a sort of exaggerated and precocious development of the heart muscle, and this is about the only kind of cardiac hypertrophy which frequently gives rise to palpitations without necessary degeneration or atrophy of the myocardium.

Now in these cases digitalis is not needed, if there be faulty conformation of the thorax; a well-directed course of gymnastics is far preferable. If there be no thoracic mal-conformation, digitalis may be tried, and if the palpitations be not quieted in the course of a few days you must find some other remedy: bromide of potassium and chloral often render real service in these cases. I have not seen any good from hydrotherapy.

I have now an important remark to make respecting the usage of this medicament. During these late years some authorities have been very precise in their statement of the indications and contra-indications of this eminently useful remedy. They have recognized in its therapeutic applications certain inconveniences, dangerous and even mortal effects. What has troubled them the most has been both the prolonged action, and the slow, tardy action of the drug. This only goes to show their ignorance of the slow, and at the same time cumulative, effect of therapeutical doses of this medicament. More than twelve years ago I divided medicaments, from the point of view of their promptitude and duration of action, into two classes; the one slow and cumulative, of which digitalis is the type; the other of medicines, like the salts of soda and potash, whose action is immediate, but which are as rapidly eliminated. In this last category may be ranged salicylic acid and the salicylates, which act with astonishing promptness, and undergo elimination almost as soon as they are absorbed. Is it a fault of these remedies—of some that they stay too long in the economy, of others that they leave it too quickly? It suffices to know these important peculiarities, that we may avoid inconveniences by not allowing digitalis to accumulate too much in the organism, and by not suppressing too soon the salicylates.

Apart from these peculiarities of action digitalis has no grave inconveniences except the difficulty of tolerance by the stomach. The immediate effects are more to be feared than the consecutive effects, which are less often seen. I have observed the latter, and I will tell you under what circumstances. In a great number of patients affected with cardiac lesions, whether of the valves and orifices or of the myocardium, chronic endarteritis and atheroma of the arteries exist. This degeneration of the blood-vessels occurs in advanced age in spirit-drinkers and in persons affected with Bright's disease. Gall and Sutton even regard arterial sclerosis as the rule in chronic interstitial nephritis. In all these cases the effects of digitalis may be nil, or even harmful. I will show you how: The action of digitalis is

manifested in an augmentation of the energy of the heart and of the tension of the blood-vessels, in a word, in a more active circulation. Now if the blood-vessels are degenerated, if the elasticity of the middle coat of the large and medium-sized arteries is compromised, if the muscular tunic of the small arterioles is invaded, the latter have lost their power of contraction, and the former their elastic retraction, and the peripheral circulation is impeded. Here digitalis is ineffectual; it may be injurious in compelling the blood to accumulate in parts the farthest removed from the heart, as in the lower extremities, where it remains stagnant in the veins, and infiltrates the tissues. This, then, is the most plausible explanation of the dangers of digitalis. Apart from these conditions, it does not occasion any inconvenience, unless in the event of mal-administration. It may, for instance, be given in too large doses, and in too small doses, just as other active medicines—chloral, bromide, salicylic acid, etc., of which one is so apt to err in the dose. Too much timidity or too much rashness; no sure and rigorous convictions; no confidence in established experience—here you have the personal bias of not a few who are clamorous for new methods of treatment, or carpers of the old.

CONVALLARIA MAIALIS.

I have been talking of digitalis and the indications for and against, according to my usual custom the last few years, of treating this medicament in my lectures, and so far have overlooked the fact that we have in *convallaria maialis* (called muguet in French, lily of the valley in English) a remedy far superior, and in every case perfectly harmless. In palpitations of the physico-dynamic order, the extract of *convallaria* succeeds marvellously. I make only one reservation. In the hypertrophies of adolescence (*hypertrophies de croissance*) I add the medicament most suitable to modify the tissue of the cardiac muscle; I refer to

IODIDE OF POTASSIUM.

One of the most useful remedies for palpitations due to hypertrophy is iodine. According to Magendie and other distinguished physicians it constitutes the most certain means for reducing the volume of a hypertrophied heart, and for removing the dangers resulting from this hypernutrition. According to this theory the iodide would be a bad remedy, doing more harm than good, for the hypertrophy is salutary and corrective, and the only means whereby an obstacle can be overcome. Happily it has no power to effect the denutrition of the heart muscle. I have employed iodide of potassium in a considerable number of diseases of the heart, with hypertrophy perfectly defined and strictly compensatory, and in all these cases the heart lost neither force nor volume. Far from that, the action of the iodide, which is so useful in cardiac dyspnoea, seems equally to aid the central peripheral circulation; the heart, far from losing energy, seems to gain in contractile force, which is always a desirable condition. So, then, the idea that iodide of potassium causes, in any sense, atrophy of the cardiac muscle, is erroneous. It benefits the hypertrophies of the period of growth as well as compensatory hypersarcosis. It is no less true that it may prove remedial in other cardio-pathies with palpitations, but without dyspnoea.

ANÆMIC AND DIATHETIC PALPITATIONS.

I come now to a question in therapeutics which seems easy of solution. I refer to the treatment of palpitations of anæmic or diathetic origin. It is so easy to cure anæmia with iron, or the arthritic diathesis with alkalies, that the remedial indications of these palpitations of blood origin seem hardly to merit serious discussion. Nevertheless, if the problem be closely scanned, its complexity will be recognized.

In the class of diathetic anæmias, as for instance, in tuberculous or cancerous anæmia, palpitations are fre-

quent. They have, however, neither signification nor duration, and do not furnish any special indication of treatment; nay, more, iron is bad for the tuberculous, as well as for the cancerous; digitalis is worse than useless, for it takes away the appetite and adds the evils of inanition to the constitutional anæmia. I do not speak of palpitations of gouty origin; they are far from being proved, at least if by the term gout we understand lithæmia.

How is it with the true anæmias? We will suppose the case of a young woman who has become anæmic in consequence of severe flooding. We will suppose a man, previously vigorous, who has lost too much blood from hemorrhoids. Both complain of palpitations, and of being easily put out of breath. Iron will infallibly increase the hemorrhages, the anæmia, and the palpitations. Hæmstatic remedies are first demanded; when you have stopped the blood losses the palpitations will disappear.

What good, on the other hand, will iron do in the case of an individual whose dietary is insufficient, whose meagre rations bespeak misery and poverty; who breathes, it may be, confined, vitiated air? Iron can do nothing for the anæmia of inanition, or even for the anæmia of professions which are attended with insufficient aëration. The cause must be removed before a cure can be realized.¹

Another kind of anæmia with grave palpitations, necessitating special care, and seeming to call for iron, is that which is consequent on seminal losses. Much, however, as iron seems to be indicated in these cases, it is seldom that it is of any marked efficacy. Every day, almost, we see patients emaciated, with sunken eyes, pale earthy countenance, complaining of inability to do mental work, of great muscular debility, generally, too, of pains in the back, and of palpitations coming on without any obvious reason, and which are not aggravated by walking, even on rising ground. These individuals are melancholy, constantly brooding over their seminal losses, which may or may not be accompanied with sexual impotence. They have been formerly masturbators, and are suffering the consequences of their folly. They suffer from palpitations (the result of sperm-waste) and can hardly be persuaded that they have not serious disease of the heart. If, confounding this sort of debility with the globular anæmias² we give iron, with—it may be—hydrotherapy, we shall very soon find our mistake. In fact, we are not concerned here with simple modification of the number, form, or composition of the red globules (in which case iron would have magical efficacy), we are concerned with a condition of general enervation and failure of nutrition. Without recommending the local treatment by urethral injections, astringent or sedative, which are of no use, and tend injuriously to fix the attention of the patient on his over-sensitive genital organs; without recommending cauterizations of the membranous or prostatic urethra, in accordance with the superannuated and dangerous practice of some surgeons, we may formulate in this manner the results of an experience which dates back a great many years, during which we have been engaged in earnest professional work.

Iron, unless we except the potassic tartrate, is without effect. Hydrotherapy is generally ill-borne; warm douches and warm baths do harm; bromide of potassium debilitates the patient too much; antispasmodics are disappointing. This is the treatment which has succeeded best in my hands: 1. One gramme (15 grains) of iodide of potassium, to be taken in two doses daily after meals. 2. With each dose of the iodide, three pills, containing each 15 centigrammes (nearly 3 grains) of aqueous extract of ergot, and 2 centigrammes ($\frac{1}{8}$ grain) of alcoholic extract digitalis. These two medicaments have a marked depres-

sant action on the reflex excitability of the spinal cord. 3. A regimen consisting principally of meat, fish, and vegetables, to give strength and repair waste. 4. Red astringent wines in moderation. 5. Abstinence from mineral waters, effervescent waters, spirituous liquors generally—especially beer—tea and coffee, and tobacco. 6. Ablutions in tepid water in the morning. 7. Moderate physical and mental labor. 8. Strict avoidance of sexual excesses; avoidance of absolute continence.

I have dwelt thus lengthily on the treatment of seminal emissions on account of the practical difficulties which are encountered in these cases, and on account of the frequency of these complaints.

I finish the consideration of anæmias with palpitations by some hints as to the treatment of chlorosis.

In this disease we witness the almost certain triumph of iron. Under the influence of this remedy—even though the case may be an inveterate one—we see rapid diminution of the weakness, sensory troubles, and breathlessness. The palpitations also abate, though slowly. There is, however, an inherent difficulty in this mode of treatment; the ferruginous medication must be continued a long time, under penalty of losing all the benefits derived. It must, moreover, be re-enforced by a substantial dietary regimen, and by the practice of hydrotherapy, which succeeds marvellously in these cases. But if the physician relax the rigor of the treatment all is lost; and yet he is sometimes obliged to compromise with his patient, who dislikes the medicine, who does not react well after the douche, or who does not tolerate the prolonged use of chalybeates. It is especially when the true palpitations predominate (I refer to the true in contradistinction to *pseudo*-palpitations, and *pseudo*-cardiodynias) that the means indicated end in failure. In these cases digitalis is contra-indicated; it troubles the digestive functions and destroys the appetite. Bromide of potassium causes a real enfeeblement after long continuance in its use. Arsenic sustains better the forces, but has no action on the palpitations. Iodide of potassium promotes menstruation and facilitates respiration, but does not correct rhythmical trouble of the heart when this trouble is due to poverty of the blood in globules or hæmoglobin.

This is the way I treat such cases. I cite the instance of a young girl, extremely chlorotic, who was referred to me for treatment by a distinguished London physician. My prescription was as follows: 1, Four times a day take 100 grammes of raw beef or mutton (preferably the latter), divested of fat, scraped and mixed with broth or pea-soup; 2, besides the raw meat, fish (fresh or salted) may be indulged in, and farinaceous vegetables; 3, for drink, water may be taken with a little brandy or wine; 4, daily ablutions of the whole body with fresh water; 5, sojourn in the country, and in a hilly region. I insisted on these details, which I consider very important. I recommended the raw meat because it is easy of digestion, and because the azotized principles of the muscular substance support the vital forces very much better than a milk and vegetable diet, and because the flesh and blood of beef and mutton contain iron combined with other principles.

Nervous palpitations.—We arrive at the diagnosis of these palpitations by way of exclusion, having eliminated the possibility of valvular or other cardiac lesions, and toxic and other alterations of the blood.

Having decided respecting the nature of the palpitations, new difficulties arise. Are they of the order of reflex nervous palpitations? Are they the expression of a general neuropathy, of a psychical trouble, or of a simple functional perturbation of the moderator or motor nerves of the heart? These questions must be answered before a rational system of treatment can be devised. It will not do to content one's self with vague theories of spasm (how high soever the authorities by whom those theories are supported), nor in practice will it do simply to ring the changes on antispasmodic remedies.

¹ The physician is often called upon to give medicine when it would be better to give food. One of the hardships which he is constantly obliged to encounter, is to treat diseases arising from mal-nutrition, when he cannot control the dietary of the patient.—T.P.A.S.

² Les anémies hypoglobulaires ou heteroglobulaires.

(a) *Reflex palpitations.*—Palpitations of reflex origin are neither so frequent nor so well demonstrated as one might imagine. Does the affection seem to be one of the digestive organs? About the only dyspeptic troubles that cause palpitations are the neuro-vascular dyspepsias and the verminous affections; the flatulent dyspepsias and the intestinal meteorisms act mechanically by displacing the heart and disturbing its functions, and are hardly to be taken into account. The true nervous dyspepsias are more difficult of cure, and the resulting palpitations are as obstinate as their cause.

The nervous disorders and the palpitations which are due to the presence of tænia in the intestines are perplexing, and the treatment is disappointing till the existence of the parasite is diagnosed; the neuro-cardiac phenomena all disappear with the expulsion of the worm.

Palpitations of reflex origin may result from perturbations of the genital organs, or lesions of the womb.

Palpitations often affect pregnant women, women suffering from amenorrhœa or uterine fibrous polypi; they may depend on a reflex irritation from the spinal cord, causing constriction of the vessels, and changes in the intravascular pressure, troubling, possibly, in this manner the rhythm, or normal frequency of the pulsations. (The above is more a matter of theory than of demonstration.)

True nervous palpitations affect the hysteric, the hypochondriac, the neuropathic, or their source is of a psychical nature (emotions, etc.); or else they constitute a trouble of innervation without determined cause. To this last category belong palpitations called essential palpitations.

(b) *Hysteric palpitations.*—Is it a case of hysteria or hypochondriasis? If the palpitations are not really subjective, *i.e.*, are real and audible to auscultation, it is necessary before all to remove the mechanical causes, such as tympanites, flatulent dyspepsia, which press the diaphragm upward and displace the heart, or trouble its functions. If it be impossible to explain the palpitations by reflex action or mechanical causes, if they are strictly nervous, they come very near to being of the psychical kind (or even of the kind called essential), and the physiological mechanism and treatment would be the same. In fact, all palpitations belong exclusively to the domain of physiology, and cannot be treated seriously and scientifically till their intimate nature is understood. Are they of the nature of spasms? Antispasmodics are indicated; but what antispasmodics? Valerian, musk, asafœtida, camphor, orange-flowers, amber, the succinates? But who, I ask, has ever known any of these drugs to cure those continued grave palpitations which begin and are perpetuated without known cause? Is the heart ever susceptible of spasm—that is to say, of a contraction—either exaggerated in force or exaggerated in duration? In the first case exhaustion would soon take place; in the second, death. Suppose, however, that those precipitate beatings, which are not spasmodic, are the expression of excitation of the nerve-centres by a physical or moral cause. In this case the excitation can only act through the intermediary of the spinal cord; but the spinal cord causes the blood-vessels to contract, it also determines an increase of vascular tension, but not palpitations. All these palpitations are, on the contrary, veritable paralysis of the par vagum or moderator intra-cardiac ganglia. When these are fatigued or exhausted, a considerable disorder results; in fact, an enormous acceleration of the heart's pulsations. The treatment ought to be based on these data; indeed, empiricism did so base it before any explanation was sought.

These palpitations have been treated: 1. By digitalis, which augments the heart's energy and the vascular tension, and slows the pulsations. It is a powerful excitant of the moderator system of nerves. 2. By bromide of potassium, which moderates the peripheral circulation, and in this way, or perhaps directly, diminishes the exaggerated activity of the heart. If the palpitations are kept up by external sensory impressions acting reflexly on

the heart, bromide diminishes the intensity of those sensory excitations by moderating the reflex spinal irritability. 3. Another remedy is veratrine, of which I shall speak when I come to treat of those grave palpitations which constitute the basis of Basedow's disease, and which seem to exhaust the heart and the patient. 4. Hydrotherapy, which in these cases is a method which is useful or dangerous according to the way in which it is applied, and according to the susceptibility of the patient.

Iron, despite its tonic power, is not of utility when administered for these palpitations, for the reason that they are not of hæmic origin. Iodide of potassium exasperates their intensity. This salt, indeed, improves the working power of the heart, but does not give tone to the paralyzed ganglia. Arsenic is preferable, but is not always sufficient.

We have never obtained any benefit from warm or cold baths or other hydrotherapeutic methods, nor even from mineral waters.

The sedatives—opium, belladonna, aconite, hydrocyanic acid—have always seemed to me to increase rather than diminish these parietic palpitations. This is easily understood. Belladonna, among others, paralyzes the moderator nerves and ganglia. The difference of action in these cases between the paralyzers and excitants of the moderator system of the heart—between belladonna on the one hand and digitalis on the other—suffices to justify our views of the paralytic nature of nervous palpitations, whether psychic or essential.

(c) *Palpitations called essential (chronic palpitations).*—There are some patients, females especially, who have palpitations for years, and after being long tormented by them, finish by living quite in harmony with the permanent disorder of their heart. I saw a short time ago a woman thirty-two years of age who had these functional perturbations for fifteen years, and to such an extent that on counting her pulse I reckoned 140 to 150 pulsations a minute, with occasional intermissions. Every kind of treatment having failed, the patient had given up all medication. She was in good health; the heart had not undergone either hypertrophy or dilatation. This fact adds to the proof—already ample—that palpitations do not exhaust the heart, and that even under the most discouraging circumstances we are warranted in giving a favorable prognosis.

A CASE OF TEARSTONE IN THE CANALICULUS OF THE LOWER EYELID.

By CHARLES J. KIPP, M.D.,

NEWARK, N. J.

CONCRETIONS, both fungoid and calcareous, are so very rarely found in the lachrymal passages, that the publication of the following case seems desirable.

Alfred B—, eight years of age, was brought to me for advice as to a painful swelling of the lower lid of his left eye. His parents stated that this eye had been "weak" for some years, but that the swelling had developed only within the last eight months.

This swelling was found to extend from the inner canthus to the punctum lachrymalis, and to involve the free edge of the lid. It was about the size and the shape of a French bean, and quite hard to the touch. The skin over it was red and œdematous, and the caruncle, the semi-lunar fold, and the conjunctiva of the whole lower lid were swollen and injected. The lower punctum was transformed into a nipple-shaped projection, about a millimetre in height, on the summit of which was a large crater-form opening, and was situated much farther from the inner canthus than normally, the canaliculus having nearly double its usual length. Pressure on the tumor caused a few drops of a whitish puriform liquid to escape from the punctum, which did not, however, materially diminish the size of the swelling. Exploration of the

canaliculus by means of No. 1 of Bowman's probes showed it to contain a stony concretion.

All doubts as to the nature of the affection having been removed by this exploration, I advised an operation for the removal of the obstruction, and consent having been given, I introduced a small Weber's knife into the canaliculus and split it in its entire length. An oval concretion of about the size of a pea was found lying loosely in the distended canaliculus and was lifted out without any difficulty. The mucous membrane lining the canaliculus was red and much thickened, and coated with thick pus. A probe could readily be introduced into and through the lachrymal sac from the canaliculus, and pressure over the region of the lachrymal sac failed to cause mucus or pus to escape from the sac into the canaliculus, thus showing that it was in a healthy condition. The distended canaliculus was thoroughly cleansed, the wound kept open for several days, and the patient directed to apply cold compresses to the lid. Under this simple treatment the tumefaction speedily disappeared, the wound closed, and two weeks after the little operation the eyelid was no larger than that of the opposite side. Since then there has been no return of the disease and the eye has ceased to be "weak."

The concretion was found to be of a grayish color in its outer layers, which were of a softer consistence than the nucleus, and were readily removed from it by a stream of water. The microscope showed this layer to be composed of pus-cells. The nucleus itself was of a whitish-yellow color, and was so hard that it required a pretty strong knife to divide it. It measured six millimetres in length and was about four millimetres thick. One half of the concretion was given to a chemist for analysis, who reported that it was composed of lime and magnesia, and carbonic and phosphoric acids, and some fatty substance. Examined microscopically, after decalcification the concretion was found to consist of a close network of very fine fibres, resembling in appearance very closely those of leptothrix buccalis. They could not, however, be stained blue by iodine.

From this description of the concretion it will be seen that it differed from those heretofore described by various authors in this, that in addition to the leptothrix elements it contained an unusually large quantity of earthy salts.

Masses of leptothrix have been found in the lower canaliculus by v. Graefe,¹ Förster,² and Narkiewicz-Iodko³; and in the upper canaliculus by Schirmer,⁴ Del Monte,⁵ and Gruening.⁶ In several of the cases a number of concretions were found together, and in all were the concretions of a cheesy consistence. Although the fungoid nature of these concretions was pointed out by v. Graefe as early as 1854, it was not till 1869 that Waldeyer,⁷ Cohnheim,⁷ and Leber,⁷ demonstrated that this fungus was a leptothrix. The identity of the plant found in the canaliculus with that of leptothrix buccalis is, however, not yet fully settled, I think, as in none of the cases except Gruening's could the fungus be stained blue by iodine. The only attempt to cultivate the fungus was, as far as I know, made by Gruening, who found, forty-eight hours after placing fragments of the concretion in glycerine, that they were surrounded by filaments of penicilium which extended to a layer of penicilium spores floating on the surface of the glycerine.

Fungoid concretions are, however, not the only ones found in the canaliculi, as is shown by Pagenstecker's⁸ case, in which a stone containing no leptothrix was removed. Whether in the tearstone removed by Desmarres,⁹ leptothrix formed the basis of the concretion is

not known; otherwise it very closely resembled the one here described.

How the leptothrix gets into the canaliculi is not known, but it seems not improbable that it is accidentally introduced into the puncta, the same as other foreign bodies, such as cilia, bits of straw, and the like, which are occasionally found here. To persons who are in the habit of wetting the edges of the lids with saliva for the removal of crusts, etc., such an accident might happen readily enough.

As regards the diagnosis of concretions in the canaliculi but little need be said. The introduction of a fine blunt-pointed probe into the canaliculus, after the punctum has been somewhat dilated by a conical probe, will in all cases and in all stages settle the diagnosis at once. The only affection for which it could possibly be mistaken, after it has given rise to inflammatory swelling of the tissue surrounding the canaliculus, would be a furuncle—a very rare affection in this part of the lid—and thus it will be readily distinguished by the history, by the elongation of the canaliculus, and the enlargement of the punctum.

The treatment pursued in the case above reported is the one to be recommended for all cases.

REPORT OF TWO CASES OF STRANGULATED FEMORAL HERNIA WITH OPERATIONS—RECOVERY.

By ALFRED NORTH, M.D.,

WATERBURY, CONN.

CASE I.—Mrs. John H—, of Waterbury, aged forty-two; has borne six children; health always good. A tumor about the size of an almond appeared in the right femoral region about two years ago, with no marked symptoms at the time of its appearance. Patient supposed it to be an enlarged gland. One year ago the patient was suddenly seized with severe colicky pains on retiring to bed. The pains were chiefly in the right inguinal region, lasted two to three hours, then disappeared. Slept soundly after this, and woke next morning well. During the last year the tumor has caused no inconvenience. Noticed that on standing much or lifting, it grew longer, but after a night's rest returned to its former size. It has never been reduced since its first appearance. It has recently acquired about the size of an English walnut.

I was called to see the patient first on Sunday morning, June 24th. She had been suffering since 2 A.M. with severe nausea and vomiting. The matter vomited was rather greenish in color, but free from fecal odor. Bowels had not moved for several days. Features somewhat pinched.

On examination I found a tumor of the size of an English walnut in the right femoral region, and traced its neck up under Poupart's ligament. It yielded no impulse on coughing and no resonance on percussion. Slight reduction effected by prolonged taxis, but nothing further could be accomplished. Ordered opium and camphor, āā gr. j. q. 4 h. , and ice-bag over tumor. Pulse, 120; temperature, 100° . P.M.: Morning symptoms aggravated. Bowels have not acted. Matter vomited has fecal odor and appearance and (to patient) a fecal taste. Temperature, $100\frac{1}{2}^{\circ}$; pulse, 120. Pills continued. Soap-suds enemata ordered.

Monday, June 25th.—Symptoms increased in severity. Vomiting persistent, but not stercoraceous to-day. Pain more severe. Bowels have not moved. Tympanites of abdomen. Ordered enema of ol. olive.

Tuesday, June 26th.—Patient seen by Dr. Axtelle in consultation. Temperature, $101\frac{1}{2}^{\circ}$; pulse, 120. Face more pinched; eyes sunken and dull; cheeks hollow and flushed. Bowels have not acted. Vomiting of bile-stained fluid with slightly fecal odor is persistent.

It was decided to give ten grains of calomel with sodæ

bicarb., to be followed in four hours with two ounces of ol. olivæ and one pint of soapsuds per rectum and to be governed by the result as to the question of operative procedure. 10 P.M.: Temperature, 102° ; pulse, 125. Bowels have not moved. Patient worse and sinking. Gave full turpentine enema in knee-chest position. This escaped in ten minutes without a trace of fecal matter. Decided to operate at once. At 12 P.M. the patient was etherized and I proceeded to operate with the assistance of Dr. Axtelle. Seized the tumor firmly and cut obliquely from the external abdominal ring, downward and inward about two and one-half inches, the point of strangulation being at the junction of the upper and middle thirds of the incision. The skin having been separated, all tissues beneath were carefully cut upon a director until the hernial sac was reached. This was about the size of an English walnut; its body was perfectly non-adherent, but the neck was adherent entirely around.¹ These adhesions were carefully broken and cut upon the director. At this stage the neck of the sac, which had been drawn out, was accidentally torn through on the proximal side of the constricting band. The entire sac was then carefully opened by the fingers and a knuckle of intestine about the size of a walnut was found strangulated, of a blackish-red color and adherent to the sac. This was carefully separated by the fingers.

The strangulated knuckle had the appearance of initial gangrene, but on close examination the results were seen to extend across the line of constriction. Sponges saturated with warm water were applied to this and soon its vessels became more injected and its color redder. Everything was thoroughly cleansed, the intestine returned, and the index finger swept around the opening, but no adhesions were found. The hernial sac was then seized and put on slight tension. The neck of the sac was stitched across with cobbler's stitch and the ends firmly tied, then brought back and tied on the opposite side, so as to include the entire neck by the latter loop. The sac was then excised beyond ligature.

The external wound was closed in the ordinary manner with silk sutures, a drainage-tube extending through, and dressed with a compress and bandage. It was necessary to inject half an ounce of brandy hypodermically during the operation to reinforce the heart's action, which became very weak.

The operation occupied two hours, and the patient was removed to bed at 2 A.M. with pulse 100 and temperature $99\frac{1}{2}^{\circ}$. Hot bottles of water were applied to feet and sides; ordered small pieces of ice in the mouth if she complained of thirst. Gave twelve minims of Magendie's solution of morphia hypodermically.

Wednesday.—7 A.M.: Temperature, 104° ; pulse, 116; respiration, 14. Slight tympanites; no pain; features less pinched; feels better. No vomiting on coming out of ether. Decided to treat as after ovariectomy. Ordered the following enema every six hours:

R. Quin. sulph. gr. v.
 Acid. sulph. aromat. gtt. v.
 Liq. opii comp. gtt. xl.
 Spts. vini Gallici $\frac{3}{4}$ ss.
 Beef-juice $\frac{3}{4}$ ss.
 M. Sig.—Enema every six hours.

Abdominal ice-water coil applied. No nourishment to be given by mouth. 2 P.M.: Temperature, $103\frac{1}{2}^{\circ}$ in vagina; pulse, 116. No nausea. Looks and feels better. 8 P.M.: Temperature, $103\frac{1}{2}^{\circ}$ per vaginam; pulse, 116. Condition and treatment same.

Thursday, 28th.—5 A.M.: Did not sleep during night. Temperature, 104° by vaginam; pulse, 120. Gave ten minims of Magendie hypodermically. After this she slept four hours. Ordered two drachms of iced milk by mouth every two hours. 6 P.M.: Temperature, 103° per vagina. Flatus escapes freely by bowel and mouth. No nausea,

no pain. Pinched look disappearing from face. Retains milk and beef-tea.

Friday, June 29th.—9 A.M.: Temperature, $101\frac{1}{2}^{\circ}$ by vagina; pulse, 90. Begins to call for food. No nausea. Nutritive enemata continued every six hours. Abdominal coil still on. Slept five to six hours during night. Eyes brighter and face less pinched. Bowels passed a thin, aqueous, yellow, fecal fluid at 9.10 A.M. To take half an ounce of milk or beef-tea by mouth every half hour. 6 P.M.: Bowels moved again. Slept during day. Temperature, $101\frac{1}{2}^{\circ}$ by vagina. Good appetite.

Saturday 30th.—11 A.M.: Temperature, $100\frac{1}{2}^{\circ}$ by vagina. Quinia and sulphuric acid omitted from enemata. One ounce of nourishment to be taken by mouth every half hour. Slept well. 6 P.M.: Temperature, 101° . Doing well.

Sunday, July 1st.—10 A.M.: Temperature, $99\frac{1}{2}^{\circ}$ per vagina. Slept well; appetite good. 6 P.M.: Temperature, $99\frac{1}{2}^{\circ}$ by vagina; $98\frac{1}{2}^{\circ}$ by mouth. Bowels moved at 11 A.M. Coil taken off for the first time; appetite good. Doing well.

Monday, July 2d.—8.30 A.M.: Temperature, $100\frac{1}{2}^{\circ}$ by vagina; $99\frac{1}{2}^{\circ}$ by mouth. Coil off all night; slept well. Nourishment by rectum stopped; appetite good.

Tuesday, July 3d.—9 A.M.: Temperature, 100° by vagina. The wound has been washed out four times daily with solution of carbolic acid. To-day the tube was taken out and wound dressed with balsam Peru. Suppurating moderately. Slept well. Appetite not so good; tongue coated and bowels flatulent. Ordered mist. rhei et sodæ, $\frac{3}{4}$ ss. every six hours.

Wednesday, July 4th.—Temperature, $98\frac{1}{2}^{\circ}$ by mouth. Bowels have not acted. Doing well. Nourished entirely by mouth.

Thursday, July 5th.—Pulse and temperature normal. Appetite good. Sleeps well. Two actions of bowels since last call; as bowels are constipated ordered a dose of rhubarb.

Friday, July 6th.—Temperature, $98\frac{1}{2}^{\circ}$; pulse, 84. Bowels acted three times after taking rhubarb. Doing well. Wound suppurating, but healing fairly well.

July 12th.—Wound almost healed. Bowels normal. Appetite good. Sleeps well. Looks and feels well. Sits up to-day for first time.

July 18th.—Wound healed and patient up and walking around.

July 21st.—Patient perfectly well, and to-day went to Peekskill, N. Y., to visit friends.

The two points to which I desire to call attention in this case are: first, the returning to the abdominal cavity of intestine at such an advanced stage on the way to gangrene; and second, the manner of obliterating the hernial sac.

CASE II.—G. F.—, German, aged fifty-two; always healthy until ten years ago; has been a caster in a metal foundry for past twenty-five years.

Patient states that about once a year for the last ten years he has been suddenly attacked with severe pains in bowels of a crampy character—with severe vomiting, lasting twenty-four to forty-eight hours or longer (patient attributed these attacks to the fumes from molten spelter, which is a kind of impure zinc containing copper, iron, arsenic, etc., he being constantly exposed to these fumes). Aside from this has always been well. Has never had hernia or any tumor of any kind.

Patient was taken in the manner described above about noon of Saturday, January 21, 1882. Attack was so severe that he had to leave work. During—or before—this attack a tumor appeared for the first time in the left femoral region. He stoutly affirms that the tumor had not existed previous to attack. I was first called to see patient early Sunday morning, January 22d. He then stated that he was suddenly attacked about noon of the previous day with severe cramps in bowels and vomiting, which was very severe and persistent, affording relief for but few minutes. These paroxysms had continued all

¹ The constriction was found to be the neck of the sac.

night without sleep. Had not sent for a physician because he supposed the attack to be like the previous ones and due to the same cause. Thought he had been in same condition many times before. When asked if he had ever had hernia or a tumor of any kind in groin, he positively stated that he had not. Not finding a satisfactory explanation otherwise for the symptoms, I made a thorough physical examination and found in the left groin, apparently at junction of inner and middle thirds of Poupart's ligament, a tumor about two-thirds the size of an English walnut, which yielded no impulse on coughing, no resonance on percussion, apparently solid and having the feeling of glandular tissue. I should certainly have regarded it as an enlarged gland in the absence of the existing symptoms. As it was, I regarded it as a hernial protrusion, and ordered an ice-bag to be applied to it, and one grain of opium to be taken every four hours. Taxis failed.

Called again at 6 P.M. and found the symptoms all much increased in severity. Features markedly pinched; vomiting stercoraceous; bowels had not been moved, although repeated large enemata had been administered since previous call. I urged an operation, as I had found all efforts at reduction to be fruitless, but patient replied that he did not want "to be cut up alive." Enemata, ice-bag, and opium continued.

At 3 A.M. on Monday morning was summoned to patient in haste, and found that stercoraceous vomiting had continued all night, pain and prostration were very great. He was begging for an operation or anything that would relieve him. Assisted only by my student and the feeble light of two kerosene lamps, I proceeded to the operation. Patient being etherized, a final effort at reduction was made, but failed. Then proceeded to operate in the usual manner. The skin being cut through, the deeper tissues were carefully and slowly separated upon a director. Hernial sac having been reached, the peritoneum was found to be perfectly normal, absolutely free from thickening or inflammation, and the hernia to be recent.

On careful search, the point of constriction was found to be at Gimbernat's ligament. This was carefully cut upward and inward as far as deemed necessary, but failing still to reduce, it was cut a second time. A second attempt at reduction failing, I introduced the point of the index finger and stretched the opening until reduction was readily accomplished. The index finger was then introduced into abdominal cavity and swept entirely around, but no adhesions found. The hernia was reduced *en masse*, the sac not being opened.

The wound was closed with silk sutures, the sutures being deep, and an attempt being made to pass them through the margins of the ring and thus effect a radical cure. This latter point probably failed. No drainage-tube was used. A compress and bandage as usual.

For the first four days the wound seemed to be healing by first intention. At this time it was found that a deep abscess had formed. This was freely opened and a drainage-tube inserted. Treated subsequently after the ordinary manner of open wounds. Treatment as to food and anodynes was such as is ordinarily adopted after abdominal surgery. Improvement was gradual after recovery from shock of operation. Flatus escaped from bowels immediately after operation. Appetite gradually returned and nausea soon disappeared. Bowels did not act till fifth day and then with no cathartic.

Discharged patient as cured on February 7th.

Ordered a truss for him on February 20th, which he has been wearing since.

July 27, 1883.—Patient has been wearing the Otto elastic truss from time of recovery until July 4, 1883, when being on vacation from work and supposing the truss to be only necessary during labor, he removed it and left it off three or four days. During this time the hernia reappeared again for the first time. The truss was replaced and has kept the hernia in place since, but it still returns on removing the truss, especially when he coughs.

Progress of Medical Science.

STENOSIS OF THE PYLORUS RELIEVED BY DIGITAL DILATATION.—The following case was reported by Professor Loreta to the Academy of Sciences of Bologna: The patient, a man forty-seven years of age, had suffered for the greater part of twenty years from imperfect digestion, distention of the stomach, sense of weight, and occasional vomiting. In 1878 he was admitted into the Bologna Medical Clinic, and treated for ulcer of the stomach. Relief ensued, but only for a short time. Eructation, a burning feeling in the throat, vomiting of undigested food, sometimes mixed with blood, increasing emaciation, and pallor of the skin and mucous membranes were noted. The man subsisted on a little milk. The distended stomach gave a clear note on percussion from the fifth rib to the umbilicus. Microscopic examination of the fluid drawn by pump from the stomach yielded no evidence of organic lesion. On palpating the emptied stomach, a tumor could be felt in the pyloric region, with smooth and elastic surface, but not very well defined limits. As the patient was steadily sinking, it was determined to resort to operation. The stomach was first washed out with an alkaline solution. The incision into the abdominal wall was commenced a little to the right of the linea alba, and extended outward and downward for six inches; the lower angle was an inch and a quarter from the ninth right costal cartilage. The omentum was extensively adherent by old inflammatory exudations. These were separated very slowly and carefully from the abdominal wall and from the surface of the stomach. This viscus was then drawn out through the wound, and the operator felt the pylorus much enlarged and of fibrous hardness. In the space between the two curves of the stomach, and at a distance of an inch and a quarter from the pylorus, an opening was made into the viscus with a stout pair of scissors through a transverse fold previously raised. The opening into the stomach was extended two inches and a half, and T-shaped forceps were used to arrest bleeding from the edges. The right index-finger was then passed into the stomach toward the pylorus, which was completely closed. The finger failed to pass into the duodenum, in spite of considerable pressure and combined lateral and rotatory movements. The left index-finger was then introduced into the stomach and used to fix the pylorus, while strong and renewed pressure was exerted to push the first phalanx of the right index into the narrow and contracted pylorus, which was then drawn forward to the external wound. Along the right index-finger the left one was also introduced into the pylorus, but these attempts failed to pull one finger from the other in spite of much force, sustained as long as possible. After resting, the operator resumed his efforts and dilated the pylorus, though he only succeeded in doing so very slowly, and by employing very great force. The dilatation was continued to about three inches. The stomach wound was then sutured with carbolized silk, the viscus replaced in the abdominal cavity, and the external wound closed with seven silver sutures. The patient was returned to bed thirty-three minutes after the commencement of the operation. On regaining consciousness he complained only of thirst and of a slight burning sensation at the wound. Small pieces of ice were given from time to time. In the afternoon the patient complained of weakness and hunger, and relished the yolk of an egg beaten up with Marsala wine, given in teaspoonfuls every half hour. The temperature throughout the day was 98°, pulse 72, respiration 26. The same kind of diet was continued. The third day after the operation the bowels acted after an enema, the fourth day some broth and light paste were allowed, the fifth day some chicken, the sixth day bread was added to the diet. On that day the bowels acted spontaneously. The wound was first

dressed on the eighth day, and five sutures removed. The incision had healed by the first intention. The two remaining sutures were removed on the eleventh day. The thirteenth day after the operation the patient's diet consisted of coffee and milk, bread, roast chicken, roast beef, eggs, and wine. He was out of bed for two hours and a half on the sixteenth day, and rapidly gained flesh and strength. Two days before the operation the man weighed one hundred and twenty-two pounds, and gained about thirty-three pounds in six weeks. He continued to enjoy perfect health when presented to the Bolognese Academy after the lapse of five months. Professor Loreta subsequently performed a similar operation in another case, and with equally good result; but in this instance he experienced much less difficulty in dilating the pylorus.—*The Lancet*, August 18, 1883.

THE CAPILLARY PULSE.—Quincke and others have called attention to a rhythmical dilatation of the capillaries, occurring synchronously with the heart-beats, in certain morbid conditions, or even in certain individuals in a state of apparent health. This pulse is seen most readily under the finger-nails, and has also been observed in the retina. It is most marked in slightly anæmic persons, and especially in sufferers from aortic insufficiency, though in neither case is it of constant occurrence. Dr. Albert Ruault, writing in *La France Médicale* of August 4, 1883, mentions a method by which this phenomenon may be conveniently studied. The head of the patient is firmly held in a suitable light, and then the forehead is rubbed for an instant by the flat of the finger-nail. If, now, the patient is the subject of a capillary pulsation, the white spot in the forehead will become reddened at the moment of cardiac systole, and at the same time the integument will be visibly elevated. M. Ruault observes that this phenomenon is nearly constant in cases of aortic insufficiency when the heart beats regularly and forcibly, but it is usually absent if the heart-action is irregular and feeble. Recent researches of Franck have shown that the mean arterial pressure in aortic regurgitation, so far from being diminished, is equal to, or greater than the normal. This indicates that the arterial system is in a state of tension. Now, says the author, if a momentary vasomotor paralysis be produced by drawing the nail across the forehead, the blood will be forced into the network of dilated capillaries at the moment of systole, and the skin will be reddened with each pulsation. This phenomenon is only met with in those pathological conditions in which there is an increased cardiac impulse, and, at the same time, a general arterial contraction. Aortic insufficiency, arterial sclerosis, and certain forms of anæmia are the conditions noted by the author as those in which the frontal capillary pulse is most readily observable.

RISE OF BODILY TEMPERATURE AFTER SIMPLE FRACTURES.—Dr. Grundler has been making a series of thermometric observations in patients suffering from uncomplicated fractures, and found in every case but one of those examined, a rise of from 2° to 4° F. above the normal. The degree of fever is in proportion to the size of the broken bone, and to the degree of extravasation. The highest temperature observed (102.5°) was in a case of fractured femur, and the lowest (100.5°) in fracture of the forearm. The rise began on the evening of the first day, and reached its highest point on the evening of the second to the fourth day.—*Centralblatt für Chirurgie*, August 11, 1883.

A POST-MORTEM CATALEPTIFORM STATE.—Brown-Séquard states that he has observed a peculiar cataleptiform condition in the muscles of the legs in pigeons, after having made a cross section of the cerebral hemispheres, the optic thalami, the cerebellum, the medulla oblongata, or the cervical portion of the spinal cord. It occurs likewise after a crushing of the head. In a short time, usually in less than fifteen minutes after death, the con-

dition manifests itself, so that the leg will remain fixed in any position in which it may be placed, even though it be opposed to the force of gravity. It has nothing to do with rigor mortis, and comes on earlier than that. It is produced most speedily after the head has been crushed. Neither the spinal cord, nor the motor nerves, nor the terminal motor plates are concerned in its production. There is rather, according to the author, a direct action of the central nervous system upon the muscles, the nature of which he hopes, by further investigations, to elucidate.—*Centralbl. für Klin. Med.*, August 18, 1883.

RECOVERY AFTER THE PASSAGE OF A RAMROD THROUGH THE BRAIN.—Dr. G. Fisher reports an instance of recovery after severe injury to the brain, which recalls the well-known case of Dr. Harlow, of Vermont, in which a tamping-iron was forced through the head by a premature explosion. In this case, an iron ramrod was discharged during the loading of a gun. It entered the back to the right of the fourth dorsal vertebra, passed upward along the ribs, and through the muscles of the neck, and forced a passage through the skull and the brain, projecting out nearly twelve inches from the left side of the head. An incision was made in the neck, and the ramrod was forced back by a hammer and extracted through the wound thus made. The patient recovered, but lost the sight in the right eye. A ramrod being propelled in the same direction through a dead body, it was found that in its course through the neck no important nerves or vessels were injured. The instrument passed through the right optic foramen, tore the optic nerve, and passed through the fissure between the frontal lobes. The destruction of brain-substance in this region was only a little over an inch in extent, and was confined to the anterior portion of the left frontal convolution. According to our present knowledge, such an injury should cause no motor or sensory disturbances. The author apprehended the appearance in time of insanity as the result of the accident.—*Centralbl. für Klin. Med.*, August 18, 1883.

EUCALYPTUS IN THE TREATMENT OF GANGRENE OF THE LUNGS.—Dr. Bonamy relates the case of a man, about fifty years of age, who was admitted to hospital suffering from cough, dyspnoea, and fever. A few days after admission the fetid odor of his breath became so extreme that it was necessary to separate him from the other patients. There was dulness in the axillary line on the left side over the middle portion of the lung. At this point there was tubular respiration and crepitant râles were audible at the end of inspiration. The sputa consisted of a black matter, detached portions of which were swimming in an abundant serous fluid. The cough was incessant, and the odor intolerable. A diagnosis was made of gangrene of the lung of superficial extent. The patient was first put upon a mixture containing carbolic acid, but no improvement following, this was replaced by tincture of eucalyptus. In two days after the last prescription the odor of the breath was much less offensive, and in less than two weeks the patient was cured.—*Le Courrier Médical*, August 18, 1883.

TREATMENT OF GRANULAR LIDS.—Dr. Arnoux claims to have met with great success in the treatment of granular lids by the following simple method: The lid is everted and wiped dry with a piece of blotting-paper. The granulations are then touched very lightly with a crystal of sulphate of copper, and immediately after a smooth cylinder of zinc is passed over them. Then the conjunctiva is carefully dried again, and, as far as possible, the impalpable black powder, which remains after the operation, is removed. The lid is then replaced, but not allowed to touch the ball of the eye for a minute or two. No subsequent cold applications are necessary, as there is little reaction if the operation be delicately performed.—*Gazetta Medica di Roma*, August 1, 1883.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PATHOGENY AND TREATMENT OF APOPLEXY.

THE old word apoplexy (Greek, a stunning blow or shock) has been retained by most writers on internal pathology to represent a congeries of symptoms due to serious interruption of the encephalic circulation. Though formerly, owing largely to the influence of Rochoux, limited to interstitial hemorrhage, and consequently applied to the rupture of blood-vessels in any organ of the body, it now denotes, in the usage of the best authorities, the sudden suspension of cerebral action produced by an internal cause affecting the circulation (vascular rupture, congestion or anæmia) and acting directly on the encephalon.¹

Rochoux's numerous observations as to the pathogeny of apoplexy had led him to conclusions more positive and rigorous than his predecessors, Morgagni and Hoffmann, had ventured to entertain. The latter recognized in cerebral hemorrhage the principal, but not the only cause of apoplexy; there had been cases in the experience of these older pathologists (and Morgagni may be said to be the founder of pathological anatomy) where the necropsy revealed nothing but an excess of serum in the ventricles, entailing, in their judgment, paralysis from pressure; other cases disclosed no appreciable post-mortem lesions, and it was found necessary to admit the existence of "nervous" or "essential" apoplexies.

The dominant influence of Rochoux and his anatomopathological studies for a time threw doubt and discredit on the so-called essential apoplexies, and it was held that intra-cranial hemorrhage, or intense congestion with hemorrhagic tendencies, was always the antecedent of the true apoplectic ictus. The first work in which public attention was directed to arterial thrombosis as a cause of local gangrenes and softenings was that of Hodgson, on "Diseases of the Arteries," published in 1814. Later, and within our own epoch, came the valuable discoveries of Virchow, Panum, and Lancereaux, relative to embolism and thrombosis, and other causes of local ischemia; and now to apoplexy from hemorrhage or from hyperæmia we must add apoplexy from anæmia. Of still later date is the startling discovery of Charcot and Bouchard that cerebral hemorrhage owes its most frequent origin to the presence in the arterioles of the cerebral hemispheres or basal ganglia, of miliary aneurisms, the result of chronic periarteritis and softening of the middle coat.

However various the conditions which give rise to the apoplectic seizure, they are all reducible in last analysis to some circulatory disturbance. The heart under hypertrophy or excitement may send too much blood to the brain, and arterioles or capillaries may give way, and an interstitial extravasation disorganize nerve-fibril and nerve-protoplasm by the very fluid destined to nourish their histological elements. This accident is more likely to take place if the encephalic vessels are enfeebled from malnutrition or disease; and endarteritis and periarteritis with resulting calcareous and atheromatous degenerations, and multiple miliary aneurisms, favor the production of hemorrhage. All inflammatory and degenerative lesions of the endocardium and blood-vessels also predispose to the formation of clots, constituting emboli or thrombi, which may cause sudden obstruction of some intra-cranial vessel, with all the ensuing apoplectic phenomena.

As a typical example of apoplexy, we will take a case of hemorrhage into the left corpus striatum. An important motor ganglion, a halting-place, as it were, for the reinforcement and co-ordination of all voluntary impulses emanating from the cortex, a ganglion, moreover, in which all the muscular groups of the body have their representative elements, is all at once deprived of blood by rupture of its nutrient artery. So far it is in the same condition as though its arterial supply had been cut off by an obturating clot. In both cases function must cease, and necrobiosis occur, except so far as collateral circulation may restore the loss. In the hemorrhagic form there is a double lesion, the interrupted circulation and the extra-vascular clot, irritating, lacerating, and compressing nerve-fibrils and nerve-cells. Hence the "shock" resulting from hemorrhage is generally more conspicuous than the shock from infarction (by autochthonous or migrating clots). Certainly in the one case an initial coma is the rule, in the other it is the exception. There is right-sided motor, perhaps also for a time sensory hemiplegia, and there may be aphasia, whether from interruption of the channels of transmission of the voluntary influx destined to the muscles of phonation and articulation, or from involvement of Broca's convolution. According to McLane Hamilton, the face will be paralyzed on the same side as the arm and leg. There is also coma, which is generally temporary. What causes the sudden loss of consciousness? This is a problem over which physiologists have wrestled. The best explanation we can give is that the local paralyzing lesion has reflexly inhibited the hemispheres also. It is the radiation to the conscious intellectual centres of the basal irritation.

As for the frequency of apoplexy, it is one of the most common causes of death in old people. The liability progressively increases from twenty upward; cases under twenty are very rare. Of sixty-nine cases collected by Rochoux,¹ fifty were beyond the fiftieth year. What percentage of people in advanced life actually die from apoplexy it is difficult to determine, deaths from this disease being recorded in city registers as deaths from paralysis (a term by no means synonymous with apoplexy, though in popular usage regarded as such), and sudden death from heart disease being every day (for want of an autopsy) referred to apoplexy.

¹ Schützenberger.

¹ Rochoux: *Recherches sur l'Apoplexie*. 1814.

The most unobjectionable classification is as follows : 1, Congestive Apoplexy ; 2, Hemorrhagic Apoplexy ; 3, Ischaemic or Necrobiotic Apoplexy. The pathogeny of the last two forms has already been touched upon. In congestive apoplexy there must be something more than simple cerebral hyperaemia to account for the symptoms ; there must be an absolute stasis in the capillaries and veins, during which rupture is imminent. The pathological condition, then, producing coma, resolution, and paralysis, is one of suspension of function from interruption of the nutrient circulation, assisted, it may be, by pressure of the engorged blood-vessels on nerve-centres and conducting strands.

The old division of serous apoplexy may as well be banished from internal pathology, as it is doubtful if serous effusion alone ever gives rise to apoplexy.¹

As accurate diagnosis is essential to exact treatment, so it would seem desirable that the physician when called to a case of apoplexy should know what kind he has to treat. Is it congestive, hemorrhagic, or ischaemic ? He has (we will suppose) ruled out narcotism, alcoholic intoxication, syncope, and hysterical as well as epileptic coma. When the coma soon subsides without leaving paralysis, it may be inferred that the attack was of the congestive kind ; the march of the affection points out the diagnosis. Moreover in apoplectiform congestion, as Racle² has shown, the jugulars and veins of the face are distended, the whole brain is engorged with blood ; the symptoms are generally cephalalgia, obtuseness of the senses, enfeeblement of the muscular functions, but true paralysis is wanting.

Between apoplexy from hemorrhage and apoplexy from an intravascular clot the diagnosis is more difficult, for the symptoms of the two forms are often identical. If the patient is old, and has beady, calcareous arteries, the presumption is that arterial thrombosis is the cause. The presumption is strengthened if, as before indicated, and as Todd, Trousseau, and Alexander Robertson long ago pointed out, there has been sudden complete hemiplegia without loss of consciousness. The presence in the patient of the tuberculous or cancerous cachexia would favor the hypothesis of thrombosis. A limitation of the paralysis to one arm, a leg, or to the face would indicate vascular infarction rather than hemorrhage. Recamier laid down some rules of diagnosis, to which unfortunately there are very many exceptions. Contracture of the paralyzed members, anæsthesia of the same parts, and enfeeblement of the intelligence, pertain to hemorrhage ; complete resolution of the paralyzed members, conservation of sensibility and intelligence, to ramolissement. According to Charcot, aphasia belongs almost exclusively to ramolissement. Embolism is more commonly met with in young patients and in the great majority of cases coincides with valvular disease of the left heart ; it comes suddenly without prodromata, the paralysis is hemiplegic, the peripheral arteries are healthy, and there are often signs of obstruction in other viscera, notably the spleen, which is enlarged and painful.³

Such are some of the diagnostic points, but, as before

said, there will be many cases where you cannot be certain in your diagnosis.

Only one or two points connected with treatment demand consideration here. Prophylactic treatment can do but little to prevent the manifestation of the more serious forms of apoplexy. We are as powerless to retard atheromatous degenerations as we are to arrest senile decay. The patient with hypertrophied heart and diseased arteries should lead a quiet, temperate life. Remedies, such as purgatives, salines, and veratrum, which diminish arterial tension, may be indicated as prophylactics whenever there is reason to fear apoplexy. The same remedies are also indicated at the time of the attack. Cold applications to the head are also of utility, and the same may be said of warmth to the feet ; sinapisms may be applied to the extremities if due caution be exercised. Bleeding should never be employed in the grave forms, and it is only indicated, and that, perhaps, rarely, in the congestive form. Sometimes venesection may be the speediest means of reducing high arterial tension, and preventing hemorrhage. Purgatives may always be tried in congestive apoplexy, and very generally they will be found to be beneficial. When there is reason to believe that hemorrhage has taken place, there are no medicaments by which we can with certainty moderate or arrest the sanguineous extravasation. If an artery have undergone occlusion we can neither promote removal of the clot, nor prevent the resulting necrobiotic softening. There is no sufficient evidence that the large doses of ergot and bromides, too indiscriminately used in all cases of apoplexy, do any good, and the same may be said of the free use of strychnia for the resulting paralysis.

KERN'S CATAPLASMATA IN THE TREATMENT OF LYMPO-SARCOMATA.

IN an article published in *THE RECORD* last spring we mentioned some facts regarding the efficacy of Kern's poultices in lympho-sarcomata. We have since had many inquiries regarding the matter, and therefore take pleasure in presenting the substance of a lecture upon this subject delivered by Professor Busch, of Bonn. Professor Busch recounts the failures which he had experienced in treating malignant sarcomata with the knife, by electrolysis, and by injections of various kinds. He had learned to recognize the value of Kern's cataplasms when a young physician in the military hospitals, where he had often seen obstinate buboes melt away under their use. These cataplasms are composed of one part mustard-flour to five parts of black soap, the whole being enclosed in a gauze bag, and applied daily over the tumor for four or five hours or longer. A very intense irritation, amounting almost to an erysipelas, is produced. The sarcomatous tumors, if fresh, soften and disappear. The results of this treatment are best shown by giving the history of a case of progressive lympho-sarcoma as described by Professor Busch :

"The patient, a very powerfully built man of thirty-five, had noticed in the beginning of July a hard swelling beneath the left angle of the lower jaw. He used water applications, presuming it to be a tonsillitis. But as the tumor grew he sought medical advice, and at first inunctions of mercurial ointment, linseed poultices, arnica, and

¹ Flint : *Prac. Med.*, p. 576.

² *Guide Clinique*, 1866, p. 94.

³ Jaccoud : *Path. Interne*, t. I., p. 148.

poppy-seed were applied. On August 13th I was called in to examine the patient and was frightened to see the appearance of the man, who two months prior had been in the best of health. An immovable tumor extended from the middle line of the neck to the vertebral column, from the inferior maxillary bone to the internal half of the clavicle. The larynx was pushed to one side of the middle line and the sternal extremity only of the sternocleido-mastoid muscles was discernible. The pulsations of the carotid could not be perceived at its proper place, as it was surrounded on its whole course. The pains of the occipital region and vertex, so characteristic in these tumors, were felt by the patient. They were occasioned by the great stretching of the posterior auricular and occipital magnus nerves. The voice had become somewhat hoarser, as the result of pressure upon the pneumogastric or recurrent nerve. With these symptoms, and in the presence of the very rapid growth of the tumor, I could only express my opinion that in all probability the patient's life would be terminated within a few weeks. If I advised any remedy, it would be the poultices of Kern. Possibly they would not benefit a great deal in this case, and should this be the case in a few days they would be discontinued. Next day I took my vacation-trip and left the patient in charge of Dr. S—, who relates to me the succeeding events. The patient endured the poultice (one to five) very well, so that (instead of having it applied, like the other patients, for four to five hours) he let it remain upon the tumor for twelve hours. In the evening the canterized region was covered with vaseline and cotton and morphine given internally. Already on August 27th, fourteen days later, an evident diminution of the tumor and greater mobility was ascertained. The cataplasmata were continued for four weeks and iodide of potassium (5 to 200) given per os. After the tumor had completely disappeared, small quantities of iodoform were brushed upon it. I saw the patient, whom I did not suppose to be still among the living, on October 3d, cured."

Professor Busch is inclined to attribute the powerful action of this remedy to the erysipelatous irritation produced by it. Professor Binz, to whom he communicated this view, thought that the oil of mustard, penetrating the softened skin, might also be a factor. At any event, the result appears as undeniable as it is extraordinary. It is not likely that all cases even of fresh tumors would have so happy a termination. It is not stated whether the tumor returned.

POWDER OF BEEF-BLOOD AS AN ALIMENTARY PRINCIPLE.

OUR ideas of nourishing invalids with irritable and weak digestive powers have been somewhat revolutionized of late years by the remarkable results of Débove and Dujardin-Beaumetz with their methods of forced feeding; and they have clinically demonstrated that proper nourishment plays no unimportant part in the therapeutics of certain chronic and convalescent states. The indications for forced feeding are presented very frequently in practice, much more frequently, indeed, than many will allow.

Though the cases in which Dujardin-Beaumetz and

Debove, the splendid results obtained by Weir Mitchell and Playfair with systematic feeding, show that its application is not limited to that class. Many cases of hysteria, anæmia, chlorosis, and convalescence from acute diseases and organic affections are accompanied by loss of appetite and even disgust for food; due in great part to the fact that the stomach has become so unaccustomed to the presence of food that it has partially lost its digestive power, the best restorative of which is food in small quantities frequently repeated. As the normal bulk of food cannot be retained or digested, the quantity must be decreased, while the nutritive value must be correspondingly increased. For this purpose we have the various meat-powders, etc., many of which are valuable, though in some cases none can be relished, or even retained, on account of their insipidity and, to some, slightly nauseous taste.

Excellent results have been obtained from the use of dried beef-blood. Recently Guerder, of Paris, has made an extensive trial of the dried beef-blood, made, however, by a new and improved process. Its advantages over powdered meat are: it is much cheaper, is superior to it in alimentary properties, representing seven times its own weight of fresh blood, and it exercises a more pronounced stimulant action on digestion and on the general organism. Whether this stimulant action is due to the extractive matters of the dried blood, to its salts, or to the large proportion of iron contained in it, cannot be positively stated. It is highly probable, however, that the iron constitutes an important factor, as its proportion of 0.30 part per 100 is sufficiently large to represent medicinal doses of iron.

It is quite certain that the reputed indigestibility of blood is without foundation, as the blood-bread in common use in Sweden is highly nutritious and easily digested, as are the blood-puddings eaten in other countries.

Débove and Dujardin-Beaumetz have not had good results from the use of dried blood. Guerder attributes this want of success to the large quantities which they administered, and their faulty methods of preparing it. Indeed, their results with his preparation have been eminently satisfactory. Guerder had administered it in 51 cases. Of this number, 44 took it well, and without inconvenience, for several weeks. Three convalescents from typhoid fever were unable to retain it at all, while to the remaining 4, all chlorotics, it was disagreeable, producing unpleasant sensations in the stomach, and was sometimes vomited unchanged after several hours. While there is, of course, no fixed dose, we should be careful that the stomach is not imposed upon. A large spoonful may be given three or four times a day to children, with a little cold coffee, and two or more spoonfuls to adults. Pepsin may be added if it causes gastric disturbance. If the patient takes other food, the blood should be taken with it, preferably in a cold liquid, and, if necessary, disguised by some aromatic, as heat develops its peculiar taste and causes difficulty of absorption.

Although excellent results have been obtained from its use in chlorosis, convalescence from acute diseases, etc., its effects upon phthisical patients have been most remarkable. When the disease was not far advanced there was invariably an early increase of strength, weight, and

appetite. It is desirable that it be still further used, in order to determine, as nearly as possible, its exact value, and certainly, with Guerder's results, it is worth the trial.

Guerder's method of preparing the dried blood is as follows: Fresh beef-blood—sheep's blood is undesirable, having a very unpleasant odor—is defibrinated and cooked for five hours on a water-bath, then slowly dried in a current of warm air at a temperature of 104° – 108° F. This demands at least three days, as every trace of moisture must be removed in order to prevent decomposition.

In this connection we may also speak of another article—highly nutritious, easily digested, and retained, and but little used—viz., raw eggs. The only objection to their use is the individual objection of the patients, and this only before the first is taken—for they seldom object afterward. The egg may be broken into a glass, care being taken that the yolk is not broken, a little salt and pepper added, if desired, and the patient takes it. He scarcely has the trouble of swallowing, for it goes down of itself. We have seen patients retain easily and even relish a raw egg, who could retain nothing else, more than six hundred being taken in one case within three or four months. It goes without saying that the egg should always be carefully selected; and, indeed, for fear that one which has seen its best days should disgust the patient, it were better to prepare it out of his sight.

EXPULSION OF THE RELIGIOUS ORDERS FROM THE PARIS HOSPITALS.

THE Government of France has for some years been engaged in a crusade against the church, and has sought by every means in its power to suppress its ministers and to place difficulties in the way of the practice of religion by believers. As long as its efforts were confined to the expulsion of the religious orders and the secularization of the schools, the matter was one of but little concern to medical men, however much they might as individuals be amused or shocked at French ideas of liberty. But, being emboldened by the success of their measures in banishing religion from the schools, the members composing a majority of the Assembly have now turned their attention to the hospitals. They first passed a decree abolishing the office of chaplain in all the hospitals. This was done on the plea of economy, and it was asserted that the patients would by no means be deprived of spiritual consolation, as, if a request were made to that effect, the nearest parish priest would be summoned. But their subsequent action in driving out the sisters showed plainly enough that they were not actuated by motives of economy. Their design was to render as difficult as possible all access of the ministers of religion to the sick and dying in the hospitals. Every medical man, no matter what his particular belief or unbelief may be, knows from experience that the quiet of mind resulting from the consolations of religion often exert a most beneficial influence upon the sick, and it cannot but be regretted that the French authorities have seen fit to reject this adjuvant to medical skill and nursing. As stated above, a further decree has been promulgated, removing the sisters from the hospitals and supplying their places with salaried nurses. To those who know the value of good nursing and have occasion to see

the efficiency of the sisters of different orders in the various hospitals under their care, this move of the French Assembly seems little short of brutal. Whatever may be thought of the danger of permitting priests to exercise their vocations in the French schools and hospitals, certainly the integrity of the Republic can hardly be imperilled by allowing inoffensive sisters to nurse the sick. Even the authors of this measure have themselves been forced to bear unwilling testimony to the worth of these devoted women. At a recent meeting of the Conseil de Surveillance de l'Assistance Publique, the question of the secularization of the Hôpital Necker came up in the order for the day. But it was decided to retain the sisters for the present, because of the possibility of an epidemic in the city. As soon as this danger is over they must go, and M. Quentin engaged to supply the places of a hundred religious by an equal number of lay nurses before the end of the year. The French ministers are a little too intemperate in their anti-clerical zeal, and both doctors and patients will have cause to deplore the unwisdom of the secularization of the hospitals.

THE ANTISEPTIC ACTION OF DRUGS WITHIN THE BODY.

THE parasitic theory of disease is one that appeals most temptingly to the imagination of the therapist. Once the particular parasite is found upon whose presence in the organism the manifestations of any given disease depend, experiments will speedily determine what drugs are poisonous to it. Then, these two factors being given, what can be more easy than the solution of the problem of cure? It is only necessary to give the remedy in quantities sufficient to kill the parasite, and our patient is cured—provided, of course, that the microbe has not had time to produce irremediable organic lesions. When the disease is a local one and admits of the direct application of the antiseptic agent, this dream may be realized. Indeed, empiricism has often, in such cases, anticipated the deductions of science, and we find the explanation of the action of long-used remedies in the power they possess of destroying certain low forms of organic life. But in the treatment of systemic or internal diseases of parasitic origin a more complex problem presents itself. If the tuberculous patient carried his bacilli about in a bottle or a test-tube instead of in his lungs or other organs, their destruction would be a very simple matter. But when it comes to killing the micro-organisms which are scattered about in various inaccessible organs and tissues of the body, the dose of the required remedy must be so great that we run the risk of killing the patient as well as his parasites. Koch has determined by experiment that corrosive sublimate is fatal to the anthrax bacteria when added to the culture fluid in the proportion of 1 part to 200,000. If given in the same proportion to the mass of blood in a man weighing one hundred and thirty pounds, it would require at least two-fifths of a grain in a single dose. Binz endeavors to show that a proportionate dose may be given by intravenous injection to animals without fatal results. He therefore takes issue with those who have denied the possibility of destroying micro-organisms within the body, without, at the same time, endangering the life of the

patient. The value of Binz's experiments is, however, questioned by Buchner (*Centralblatt für Klinische Medizin*, July 14, 1883). The latter claims that corrosive sublimate in the proportion of 1 part to 200,000 of the animal fluids is fatal to the organism, and he refuses to accept the conclusions of Binz in disproof of his assertion. Corrosive sublimate, he says, enters into chemical combination with the albumen of the blood, forming an albuminate of mercury. This substance, although remaining in solution, is less readily diffusible and less capable of endosmosis, and hence there is no certainty that it becomes equally distributed in all the tissues. Further, the bichloride, by its transformation into albuminate of mercury, is robbed of a great part of its poisonous action. This is indicated by the less irritant action, and therefore the less immediately injurious effect upon the cells, of the latter salt when injected hypodermically. Buchner has found that double the quantity of albuminate of mercury is required to produce the same effects upon bacteria as are caused by a given amount of the bichloride. He does not deny that certain diseases are cured by the internal administration of antiseptic remedies, such as quinine, bichloride of mercury, salicylic acid, etc. But he asserts that they act, not as antiseptics, but in some other way, possibly by increasing the power of resistance of the organism to the action of the specific parasite. He says that were quinine to act as an antiseptic within the tissues, it would require in the average individual a dose of at least three ounces. Arsenic, again, possesses feeble antiseptic properties, yet its action in small doses in malaria is undoubted. It cannot be due to its poisonous action upon the malarial bacteria, and must, therefore, be owing to some specific effect whereby the tissues are enabled to resist and throw off the poison. The author concedes that there may be some relation between the property possessed by a drug of destroying micro-organisms outside of the body, and its known value as a remedy in disease, but he denies that the action in the two cases is the same. He thinks that newly discovered antiseptics should always be given tentatively in parasitic diseases, and believes that thereby many valuable specifics may be added to our list. But the attempt to secure an antiseptic action of any drug within the body is not only useless, but fraught with danger to the life of the patient.

THE RECORD'S CABLE REPORT OF THE BRITISH MEDICAL ASSOCIATION.

THE *British Medical Journal* contains the following appreciative notice of THE RECORD's cable report of the meeting of the British Medical Association. "The New York MEDICAL RECORD publishes in its number of August 4th an excellent summary of the proceedings of the recent meeting of the British Medical Association at Liverpool, forwarded by daily despatches through telegraphic cable. The outlay on this enterprising report must have been considerable, and we may refer to it with satisfaction, not only as an admirable example of journalistic enterprise, but as a striking evidence of the strong and growing feeling of sympathy and international interest which characterizes the relations of the profession in Great Britain and America. THE MEDICAL

RECORD speaks in terms of the most courteous compliment and congratulation of the organization of the British Medical Association and its results, and refers with special satisfaction, and in eulogistic terms, which we recognize gratefully without reproducing, to the words in which the health of our guests was proposed at the annual dinner, and the warm friendship felt and shown toward our American guests."

KAIRINE—THE LATEST RIVAL OF QUININE.

THIS new antipyretic agent has as yet attracted but little notice in this country, although it has for some time been the subject of investigations by our German confrères. It was discovered about a year ago by Dr. Fisher, of Munich, who states that it is the hydrochloride of oxyethylquinolinehydrid. If there is anything in a name, there ought to be no doubt of the value of the remedy, but this is a busy world, and life is short, so the name has been mercifully changed to kairine. The testimony thus far collected, concerning the properties of kairine, is somewhat conflicting. Dr. Girat has experimented largely with it on animals, and has found its lowering effects upon temperature to be very constant. It also slows the pulse and diminishes the number of respirations. He administered the drug hypodermically, and states that the member into which the injection was passed became paralyzed. The sensibility of the part was blunted, passing sometimes to complete anæsthesia. Elimination occurs, in part at least, by the kidneys, and is tolerably rapid, the presence of the substance in the urine being determined within twenty-five minutes after its administration. The urine acquires a dark green color. According to Dr. Girat's experiments, the toxic dose is said to range between one and two grains to the pound of the weight of the animal. Dr. Filehne (*Berliner Klinische Wochenschrift*, April 21, 1883) concludes, from observations made by him in disease, that kairine is a most valuable febrifuge, effective in all conditions accompanied by elevated temperature. He has employed it with success in typhoid fever, acute articular rheumatism, septicæmia, phthisis, and pneumonia. He recommends its use tentatively in commencing doses of seven and a half grains per hour for four hours, or until the temperature has fallen to 100° F. The dose is then lowered to three or four grains, to be again increased when the temperature begins to rise. It is stated that by carefully experimenting during the first day, the proper dose may be ascertained for each individual, which may then be adhered to in the subsequent treatment. These favorable effects have not been recorded, however, by all observers. Professor Riegel reports most unsatisfactory results in the treatment of pneumonia by kairine (*Allgemeine Medicinische Central-Zeitung*, July 28, 1883). He was unable to obtain any notable reduction of temperature by four hourly doses of seven and a half grains each, and even larger amounts were often powerless to produce the desired effect. Even when he succeeded in reducing the temperature nearly to the normal, it often rose again in spite of repeated doses of the remedy. As regards the pulse, it was by no means reduced in frequency as the temperature fell, and, furthermore, it was much weakened. An improvement in the subjective sensations

of the patient, as described by Filehne, was not met with, but, on the contrary, there was repeatedly observed such a depression, amounting almost to collapse, that it was necessary to discontinue the kairine and resort to stimulants. The same effect has been noticed by Seifert. Professor Riegel concludes that kairine is a dangerous remedy, in pneumonia at least, chiefly because of its depressing action upon the heart, and he cautions against its use in asthenic forms of the disease. It is evident that further trials are necessary before the exact value of this new substitute for quinine can be determined, and it is doubtful whether it will be able to maintain the high character as a safe and certain antipyretic which the early experimenters claimed for it. In fact, few new remedies answer fully to the expectations of their introducers.

THE WISCONSIN STATE MEDICAL SOCIETY AND THE ISOLATION OF CONSUMPTIVES.

As will be seen in the opposite column, the Wisconsin State Medical Society, during its annual session last week, passed a resolution virtually declaring consumption to be an infectious disease, and urging the necessity of the proper isolation and disinfection of those suffering from it.

This action will be regarded, we believe, as somewhat premature. Phthisis is, to be sure, now considered by pathologists as a tubercular infection, and the possibility of its very occasional contagiousness is not to be denied. But the profession is by no means yet prepared to accept the view that the disease is actively or dangerously contagious. Medical societies, therefore, by intimating that it is so, do an act that is sensational, weak, and injurious to their prestige.

News of the Week.

THE AMERICAN PHARMACEUTICAL ASSOCIATION held its annual meeting at Washington, D. C., on September 10th, 11th, and 12th, the President, Charles A. Heinath, in the chair. Mr. Sloan, from the Committee on Drug Market, submitted a report containing statements and tables reviewing the fluctuations of the market for the year, and stating, among other things, changes made in the tariff on drugs. Mr. J. W. Colcord, of Massachusetts, offered a resolution directing the Committee on Legislation to ask Congress to appropriate \$25,000 for the introduction of foreign medical plants into this country, and for the propagation and care of home plants. He said that the climate of the United States presents peculiar advantages for the growth of many foreign medical plants, and that Dr. Loring, Commissioner of Agriculture, favored the proposition. The Ebert prize was awarded to J. U. Lloyd, of Cincinnati. The following officers were elected for the ensuing year: President, W. S. Thompson, of Washington; First Vice-President, Dr. Charles Rice, of New York; Second Vice-President, T. H. Masi, of New York; Third Vice-President, E. W. Runyon, of San Francisco; Treasurer, Charles A. Tufts, of Dover, N. H.; Permanent Secretary, J. M. Maisch, of Philadelphia; Reporter of Progress of Pharmacy, C. L. Diehl, of Louisville, Ky.

THE ANNUAL MEETING OF THE WISCONSIN STATE MEDICAL SOCIETY.—This meeting was held at Milwaukee, September 5th, 6th, and 7th. Dr. Mason, of Milwaukee, First Vice-President, was in the chair. About sixty members were present. An unusually large number of papers was read. The officers elected for the ensuing year were: Dr. Dodson, of Berlin, President; Dr. E. W. Bartlett, First Vice-President; Dr. Jenkins, Second Vice-President. Dr. Reeves was continued in his office of Permanent Secretary and Treasurer.

The Society took official action in regard to the matter of color-blindness, urging that there be some legislation by the State regarding it.

The Society also passed the following resolution:

"Resolved, That in consideration of the advance as to a knowledge of the causes of consumption and of the now known infectious character of the disease, we use all the means in our power to have the phthisical members of families as much as possible separated from the healthy members, and also that we recommend the State Board of Health to take means to have such persons separated from intimate association with the well in our public institutions."

During the session, Dr. F. A. Marsden was suspended for having distributed patent medicine circulars.

The Society adjourned to meet on the first Tuesday in May, 1884.

THE WELL-KNOWN ANATOMIST, PACINI, recently died at Padua.

THE FLOATING HOSPITAL OF ST. JOHN'S GUILD has closed its work for this season. Forty-four excursions were made, on which 29,189 children and mothers were carried. The greater number of these were sent by dispensaries and the Board of Health.

THE TWELFTH ANNUAL SESSION OF THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, MEDICAL SECTION.—This Association held its annual meeting at Rouen, August 16th, 17th, and 18th. The Honorary President of the Medical Section was M. Verneuil; the President, M. Duploux, of Rochefort. Among the more prominent persons present were Drs. Huchard, Landowsky, Voisin, and Jolly. A paper was read by M. Pineau "Upon a New Fact Regarding the Transportation of Typhoid Fever." M. Deshayes reported a unique case of "Herpes Zoster following the Right Fifth Nerve, and accompanied by Neuralgia." M. Huchard read an elaborate paper upon "Hæmoptysis Occurring in Rheumatics who are not Tuberculous." M. Gallard introduced a discussion upon the "Theory of Menstruation." M. Gallard read the history of a curious case, which he considered "Tetanus of Gastric Origin." The patient, who suffered from persistent dilatation of the stomach, was subject to convulsive attacks of the limbs, the face and trunk not being involved. These attacks ceased under treatment of the gastric condition. MM. Audrien and Raoul Bravais presented a communication upon "Antimicrobial Medication;" under the name of "anti-epidemic granules," they presented some pills composed of "monosulphure de magnésium anhydre." These they claimed, when taken in proper doses, would remove the susceptibility to infectious disease. M. Mallez showed the Society a "Surgical Pantograph," by which the size

and contour of a body could be measured. M. Landowsky read a paper upon the therapeutics of "Piscidia Erythema," but communicated nothing new. M. Voisin made a plea for the use of the hypodermic method of giving medicines in nervous and mental diseases. M. Tessier tried to show that "typhoid fever" varied in amount (at Lyons) in accordance with the rise and fall of the subterranean or well-water. M. Cerné reported a case of "Spontaneous Gangrene in a Patient with Polyuria and Phosphaturia." The subject of "Alternating Diabetes" was brought up and cases where there was, at different times, glycosuria, polyuria, azoturia, were cited. M. Jolly read a paper upon "The Primary Function of the Phosphates in Living Beings." M. Gouguenheim read a paper upon "The Indications for Tracheotomy in Tubercular Laryngitis," in which he took the ground that the operation was rarely needed, and only in certain cases where there is rapid caries or infiltration. M. Beauregard read a paper showing the favorable results of "Osteotomy in the Treatment of Genu Valgum in Infants." He had never had any consecutive accidents in doing this operation.

THE INTERNATIONAL MEDICAL CONGRESS.—We have received a letter from Dr. Lange, Secretary-General of the International Medical Congress, which meets at Copenhagen next August, in which we are informed that the General Organizing Committee, formed for the preparatory work, is composed of the following members, living either in or near Copenhagen: President, Professor P. L. Panum; Secretary-General, Professor C. Lange; Secretaries, Dr. O. Bloch, Dr. C. J. Salomonsen, and Surg.-Gen. Joh. Møller; Honorary Treasurer, Professor E. Hansen Grut; besides the presidents and special committees of the Sections, viz.: Anatomy, Professor Chievitz; Physiology, Professor P. L. Panum; General Pathology and Pathological Anatomy, Professor C. Reisz; Medicine, Professor F. Trier; Surgery, Professor Holmer; Hygiene and State Medicine, Dr. E. Hornemann; Military Surgery and Medicine, Director-General of the Medical Department of the Army Salomon; Mental and Nervous Diseases, Professor Steenberg; Obstetric Medicine and Surgery and Gynecology, Professors Stadfelt and Howitz; Diseases of Children, Professor Hirschsprung; Ophthalmology, Professor E. Hansen Grut; Diseases of the Skin and Syphilis, Professor Haslund; Diseases of the Ear, Dr. W. Meyer; Diseases of the Throat, Dr. W. Meyer. The special committees formed for the aforesaid Sections have, when they found it useful, completed their number by members living outside Copenhagen, partly in Denmark, partly in the other Scandinavian countries. The Organizing Committee is now at work preparing a programme.

DR. CALVIN ELLIS has resigned his position as Dean of the Harvard Medical School. Dr. H. P. Bowditch, it is said, will be elected in his place.

THE CANADA MEDICAL ASSOCIATION held its annual meeting at Kingston, Ont., September 5th, 6th, and 7th.

THE ENGLISH CHOLERA MISSION TO EGYPT.—Letters received from the medical men sent out from England to Egypt are, says the *British Medical Journal*, very discouraging. It does not seem likely that sanitary meas-

ures for the prevention of future outbreaks of cholera can be adopted for a long time to come. It is claimed that cholera has been in Egypt since 1865, and that cases occurred near Damietta last May. Antecedent to cholera, there had been an epidemic disease among horses, typhus carbunculus, so called, and next bovine typhus, which killed its thousands. The difficulties of carrying out efficient sanitation are found to be enormous. The habits of men, women, and children are such as habitually to defile their habitations and the surrounding ground. As to the Medical Department, it has been found to be in a far worse state than could have been expected. The registers of deaths in the villages are made out by the barber; the cases, in a large proportion, are never seen during life, and the barber enters whatever disease comes first to his imagination and his pen. The Egyptian medical officers are, as a body, found to be wretchedly paid, and very incompetent; cowardice and neglect of duty are very rife among them. They have not the confidence of the fellaheen, who seldom seek their advice, and the Arabs never, without exception. The hospitals are wretched, tumble-down hovels, filthy in the extreme, and the beds not less so. The lunatic asylum at Abbassieh is filthy beyond description, and its management indescribably bad.

ASSOCIATION FOR DISEASES OF THE RESPIRATORY ORGANS AND CLIMATOLOGY.—A meeting for the purpose of organizing the national "Association for Diseases of the Respiratory Organs and Climatology," will be held in the parlors of the Academy of Medicine in this city (12 West Thirty-first Street), on Tuesday, September 25th, at 10 A.M.

COLLEGE OF MIDWIFERY, N. Y.—The following changes have been made in the Faculty: Dr. Sarah E. Post has been appointed Professor of Physiology in the place of Dr. John Alsdorf, who has taken the chair of Diseases of Pregnancy and Parturition. Dr. Henry F. Hessler has been appointed Professor of Clinical Midwifery and German Instructor in Obstetrics. The sessions have been extended to six months—three months of didactic instruction, and three months of clinical work.

NEW BRUNSWICK MEDICAL SOCIETY.—This Society held its third annual meeting at St. John recently, when about fifty members were present. The following officers were elected: *President*, Dr. Vail; *First Vice-President*, Dr. Walker; *Second Vice-President*, Dr. Patterson; *Secretary*, Dr. G. M. Duncan; *Corresponding Secretary*, Dr. Coleman; *Treasurer*, Dr. Nevers. Dr. Steves, of St. John, proposed that a New Brunswick quarterly medical journal be established under the auspices of the Society. The next meeting will be held in St. John, in July, 1884.

THE ATLANTIC JOURNAL OF MEDICINE is a new monthly journal recently started in Richmond, Va., and edited by Drs. Robert B. Stover and Henry G. Houston.

THE CHOLERA EPIDEMIC IN EGYPT seems to be at an end. During its whole course—that is, in about three months—it has destroyed nearly thirty thousand lives.

PROFESSOR SCHWALBE, of Königsberg, has been called to Strasburg.

Reviews and Notices.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF TENNESSEE. Fiftieth Annual Session, held at Nashville, Tenn., April 10 and 11, 1883.

THIS year's report has appeared with commendable promptitude, wherein it contrasts favorably with that of last year and with society reports in general. The volume contains several papers of interest and of refreshing brevity, and also the code of ethics of the American Medical Association. The society contains three hundred and thirty-eight members, and has lost three members by death during the year.

REPORT OF PROCEEDINGS OF THE ILLINOIS STATE BOARD OF HEALTH. Quarterly Meeting, held at Springfield, Ill., June 29, 1883.

THE Illinois State Board of Health is doing a good work in seeking to rid the State of quacks. Its efforts hitherto have been productive of good results, and judging from the secretary's report, presented at this meeting, it intends to keep up the fight until all the travelling and advertising charlatans have sought refuge in other less-favored localities. Further than this, the board endeavors, by the only means in its power, expostulation with the offenders, to discountenance the practice of giving medical testimonials concerning the virtues of various nostrums and patented surgical appliances. May the good work go on.

TRANSFUSION: ITS HISTORY, INDICATIONS, AND MODES OF APPLICATION. By CHARLES EGERTON JENNINGS, L.R.C.P. London: Baillière, Tindall & Cox, 20 King William Street, Strand. 1883.

IN this little volume of sixty-nine pages the author has called attention to certain cases where transfusion would, as a rule, afford only temporary benefit, as well as to those in which this measure is demanded on the part of the practitioner, and is generally attended with success. His remarks are also supported by clinical experience and by statistics. In addition, the methods of application (illustrated), and the favorable conditions necessary to the operation are also presented, together with the immediate causes of failure, the several attending dangers, and the means of avoiding them.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY for the Year 1883. No. 3, Vol. VIII. Lansing: W. S. GEORGE & Co. 1883.

THE eighteenth Annual Meeting of the Michigan Medical Society was held at Kalamazoo, Mich., May 9 and 10, 1883. The usual business of annual meetings was transacted, the usual papers read, and the usual animated discussion over points of order held. The volume before us contains, in addition to the scientific papers, an amusing squib in verse by Dr. E. B. Ward, the title of which is "Pro Bono Professionis."

BACTERIA AND THE GERM-THEORY OF DISEASE. By DR. H. GRADLE, Professor of Physiology, Chicago Medical College. 8vo, pp. 219. Chicago: W. T. Keener, 96 Washington Street. 1883.

THIS volume comprises a series of eight lectures on the above subject, delivered at the Chicago Medical College by the author. The subject is, moreover, very fairly handled in each essential point. Beginning with the relation of the germ-theory of disease to the animal system, the examination and the cultivation of bacteria, fermentations, putrefaction, are then dealt with, followed by the action of bacteria in digestion, inoculation of germs, the germicide treatment, etc. Surgical infection is then taken up in its various forms. The chapter on tuberculosis, its infectious character and its inoculability, is not among the least interesting. The fevers, diphtheria, syphilis, and various local diseases, also receive

attention. Finally, the importance of the germ-theory of diseases in its relation to the future is considered.

The work is altogether one of undoubted interest, not only from the great importance of its subject, but chiefly from the large amount of original work done, and the completeness with which it is presented, even in minute detail; the latter being especially prominent, when it is remembered that most of our published information on this topic is, as a rule, in the form of abstracts from foreign journals.

EXCISION OF THE KNEE-JOINT, WITH REPORT OF TWENTY-EIGHT CASES. Illustrated by Thirteen Photo-lithographs and Wood Engravings. By GEORGE EDGEWORTH FENWICK, M.D., C.M., Professor of Surgery McGill University; Surgeon to the Montreal General Hospital. 8vo, pp. 68. Montreal: Dawson Brothers. 1883.

DR. FENWICK regards the operation of excision of the knee-joint as undeserving of the disfavor into which it has fallen, and he endeavors in this little volume to gain for it somewhat more consideration at the hands of his professional brethren than it now receives. His cases are comparatively few—twenty-eight in eighteen years—but the results are exceptionally good. Indeed, had other surgeons met with such uniform success, the operation would never have needed an apologist. The author's method of operation consists briefly in sawing off only so much of the joint surfaces as is absolutely necessary, preserving the epiphyses as far as possible. The articular end of the femur is rounded and made to fit into the hollowed-out head of the tibia. The surgeon's personal attendance to the after-treatment is insisted upon. It is to this method of section of the bones that the author attributes much of his success, and he hopes to see its general adoption in order that others may share in his good fortune, and unite with him in upholding the reputation of this operation.

THE PRINCIPLES AND PRACTICE OF MEDICAL JURISPRUDENCE. By the late ALFRED SWAINE TAYLOR, M.D., F.R.S., Fellow of the Royal College of Physicians of London. Third edition. Edited by THOMAS STEVENSON, M.D. (London), Fellow of the Royal College of Physicians of London, etc. 2 vols., 8vo, pp. 1,359. Philadelphia: Henry C. Lea's Son & Co. 1883.

NO one need doubt at the present day that Taylor's work is the leading one on medical jurisprudence in the English language. It was quite fortunate for both medical and legal professions that the author in his last edition brought his treatise so thoroughly up to the times and so carefully and judiciously interpolated all the leading cases and decisions pertaining thereto. It was in that respect more than an improvement on the previous edition, as it was essentially revised from beginning to end, while much valuable matter was added under the head of poisons, wounds of throat, blood-stains, cicatrices, asphyxia, abortion, infanticide, insanity, and life insurance. Thus the work was left by its author at the time of his death. The task of subsequent revision has been undertaken by the former colleague of Dr. Taylor, Dr. Stevenson, who has shown himself in every way fitted for the task. He has evidently gone over the text with great care for the purpose of adding new facts of evidence under their respective headings, while steadily keeping in view the necessity of not increasing the number of pages. This has compelled him in many instances to curtail some of the chapters, notably those on medical evidence.

The chapters on poisoning have been in many parts entirely rewritten, the necessity for which can be readily understood by the recent advances made in this department of forensic medicine. New and illustrative cases have been added in many other departments. The editor has very wisely used his privileges of adding facts without in any way interfering with the author's views regarding the main principles upon which all proper medi-

cal evidence is founded. The volumes are published in good style.

ANATOMY, DESCRIPTIVE AND SURGICAL. By HENRY GRAY, F.R.S., Fellow of the Royal College of Surgeons, etc., with Introduction on General Anatomy and Development by T. A. Holmes, M.A. Cantab. With drawings by H. V. Carter. Edited by T. Pickering Pick, Surgeon to St. George's Hospital. New American from the Tenth English Edition. To which is added Landmarks, Medical and Surgical, by Luther Holden, F.R.C.S., with additions by W. W. Keen, M.D. 8vo, pp. 1,023. Philadelphia: Henry C. Lea's Son & Co. 1883.

THIS well-known work comes to us again as the latest American edition from the tenth English edition. As its title indicates it has passed through many hands, has received many additions and revisions. Consequently the publishers are content to issue it more as a reprint than as an improved edition. There is good reason for the latter course, as the work is not apparently susceptible of more improvement. Taking it all in all, its size, manner of make up, its character of illustrations, its general accuracy of description, its practical aim, and its perspicuity of style, it is the anatomy best adapted to the wants of the student and practitioner.

Reports of Societies.

STATE MEDICAL SOCIETY OF VIRGINIA.

Fourteenth Annual Session, held at Rockbridge Alum Springs, Va., September 4, 5 and 6, 1883.

(Continued from p. 271.)

AFTER the transaction of society business at the session of Thursday, September 6th, DR. J. J. CHISOLM, of Baltimore, Md., read a paper on

THE REMOVAL OF FOREIGN BODIES IN THE EAR.

He stated that the little bony projections on the exterior surface of the drumhead have often been mistaken for foreign bodies, and the attempt to extract them on the part of the general practitioner has produced disease and permanent deafness. To illustrate the common occurrence of attempts to remove these ossicles for extraneous bodies he cited several cases which had come under his notice. He believes that there are numerous cases of individuals living many years with foreign bodies in the ear without knowledge of the fact, and stated that most instances of inflammation of the ear were due more to injudicious attempts at removal than to the presence of the body itself. He had never seen, in all his experience as a specialist, a case of foreign body in the ear, not interfered with by another person, which he was unable to remove by the careful use of a syringe and warm water. In all instances of leguminous or other foreign bodies that increase in size by the absorption of water in the ear, he recommends

THE FILLING OF THE CAVITY WITH ALCOHOL TO PRODUCE SHRINKAGE BEFORE THE USING OF THE SYRINGE.

He uses pure alcohol.

DR. SPIERS GIBSON, of Staunton, exhibited

AN EXTENSION AND SUSPENSION SPLINT

of his own invention for treatment of fractures of long bones.

DR. L. McLANE TIFFANY, of Baltimore, Md., read a paper on

PLASTIC SURGERY OF THE FACE,

and after careful description of the anatomy of the face he instanced the different plastic operations of that por-

tion of the body. He referred to the peculiarity of the fact that the facial bones will often not become necrosed when denuded of their covering, differing from the bones of the trunk and extremities. He stated that he always adopted the old-fashioned method of marking off the flap before cutting in plastic operations, preferring tincture of iodine for that purpose.

He employs hot water as a hæmostatic almost invariably in surgery of the face, and uses iodoform and absorbent cotton on all granulating wounds of that part. He employs only the simple interrupted suture by means of silver wire. He laid great stress upon the necessity of bringing together the lips of all wounds of the face, simply in apposition without the slightest tension; and stated that he always makes a flap for the hare-lip operation, contrary to common usage. He gave full details of his mode of operating in the mouth. Dr. Tiffany exhibited several large plates and photographs of cases illustrative of his paper.

DR. JOHN N. MACKENZIE, of Baltimore, Md., read a paper on

DEFLECTION OF THE NASAL SEPTUM

and its treatment. He believed that a tendency to this condition was frequently inherited. The condition narrows the nasal orifice and increases the pharyngeal opening, and the irritation by reflex action on the vasomotor nerves often causes aural disease. Ozena is frequently produced from the condition by the air remaining in the nasal cavity imperfectly changed and putrescence invited. He described the present form of modification or replacement of deflected bony septum, which has for the past few years been known as Steel's modification of Adams' operation, and showed that Dr. Bolton, of Richmond, Va., some years before Steel's paper on the subject, described the identical method in his own practice in an issue of the *Richmond Medical Journal*. Dr. Mackenzie was emphatic in his advice to the members to look closely after the sequelæ which follow the condition named, and stated that it was his invariable rule to begin an examination of the throat and ear with a careful exploration of the nasal passage and retro-nasal space.

DR. J. A. WHITE, of Richmond, showed a selection of instruments and dilators for operating on deflected nasal septum and made a few remarks upon the operation, giving his reasons for his

EMPLOYMENT OF SEATANGLE BOUGIES FOR HOLDING THE SEPTUM IN PLACE

after replacing. He related the details of cases in which he had lately used Seiler's galvano-cautery for ulcer of cornea in pannus and granular lids as well as deflected septum. Dr. Wright also showed a small mass of what appeared to be iron-ore, taken from the nose of a lady over forty years of age, the history of the case showing that the foreign body was introduced in early childhood.

RUSSIAN BABIES.—A correspondent of the *New York World*, speaking of Russian babies, describes as follows what one sees in the house of a Russian peasant: He looks curiously at one odd little bundle laid upon a shelf, another hung upon the wall on a peg, a third slung over one of the main beams of the roof, and rocked by the mother, who had the cord looped over her foot. "Why, that is a child!" cries the traveller, with a feeling similar to that experienced on treading upon a toad which was supposed to be a stone. "Why, what else should it be?" answers the mother. Having learned so much in so short a time, the inquisitive traveller wishes to inform himself about the habits of the creature in the bundle; but his curiosity being somewhat dampened by the extreme dirt of the little figure, he inquires of the parent when it was washed. "Washed?" shrieks the horrified mother, "washed! what, wash a child? You'd kill it."

Correspondence.

THE GERM-THEORY IN ITS RELATIONS TO MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Almost simultaneously with my recent article in THE MEDICAL RECORD (August 18, 1883) upon the unreliability of any theory yet advanced as to the ultimate cause of malaria, I find two papers pertinent to the same subject in the *Popular Science Monthly* for September. One of these deals with the germ-theory of disease, being a lecture delivered before the Chicago Philosophical Society by Professor H. Gradle, M.D. The other, by Professor A. F. A. King, M.D., entitled, "Insects and Disease—Mosquitoes and Malaria," being the abstract of a paper on "The Prevention of Malarial Disease," read before the Philosophical Society of Washington.

Permit me to briefly review some portions of these two articles.

Speaking of the "destroyers" which cause disease, Professor Gradle remarks: "They are no longer invisible creatures of our own imagination, but with that omnipotent instrument, the microscope, we can see and identify them as living beings, of dimensions on the present verge of visibility. The study of these minute foes constitutes the germ-theory."

From this quotation I presume the doctor employs the term "destroyers" as equivalent to "germs." He acknowledges, however, that they are only of dimensions "*on the present verge of visibility*" by the microscope. I agree with him there, if he means that they have not yet been actually seen with any degree of certainty. Still he proceeds to say that the germ-theory "has substituted a tangible reality for idle speculation and superstition, so current formerly in the branch of medical science treating of the causes of disease." He says truly that "obscure chemical changes, of which no one knew anything definitely, or 'impurities of the blood,' a term of similar accuracy and convenience, were accused, while with regard to contagious diseases medical ignorance concealed itself by the invocation of a 'genus epidemicus.' The germ-theory, as far as it is applicable, does away with all these obscurities."

I cannot at all subscribe to the last dogmatic assertion. I am quite sure that there are many zymotic affections (that class to which the germ-theory is peculiarly applicable) in whose study "medical ignorance" has no other alternative than simply to recognize and acknowledge "impurities of the blood," whose character has not yet been demonstrated; or to invoke a "genus epidemicus" as the only explanation, however unsatisfactory, yet afforded, for a sudden outbreak and wide extension of some particular disease. As an example I may cite diphtheria.

Professor Gradle asserts that bacteria belong to the *lowest* order of fungi. He remarks that "no error has retarded more the progress of the germ-theory than the false belief that the bacteria of putrefaction are identical with the germs of disease." What, therefore, may it be asked, are identical with the germs of disease? and must not germs be regarded as fungi?—or if not, what are they?

Dr. Gradle goes on to say that "in order to prove the bacterial origin of a disease two requirements are necessary: First, we must detect the characteristic bacteria in every case of that disease; secondly, we must reproduce a disease in other individuals by means of the isolated bacteria of that disease. Both these demonstrations may be very difficult. Some species of bacteria are so small and so transparent that they cannot be easily, if at all, seen in the midst of animal tissues. This difficulty may be lessened by the use of staining agents, which color the bacteria differently from the animal cells. But it often requires long and tedious trials to find the

right dye. The obstacles in the way of the second part of the proposition mentioned are no less appalling. Having found a suspected parasite in the blood or flesh of a patient, we cannot accuse the parasite with certainty of being the cause of the disease, unless we can separate it entirely from the fluids and cells of the diseased body without depriving it of its virulence. In some cases it is not easy, if possible, to cultivate the parasite outside of the body; in other instances it can be readily accomplished. Of course, all such attempts require scrupulous care to prevent contamination from other germs that might accidentally be introduced into the same soil."

By employing the expression "other germs" in the foregoing paragraph he can imply nothing else than that bacteria are germs, although previously he has expressly insisted that they are not.

Then bacteria-rods "form seeds or spores, as they are termed." Considering the minuteness of bacteria, and the consequent infinitesimal size of their spores, "which germinate again in proper soil," we are led to inquire once more, How about the germs? Almost every microscopist is familiar with the several forms of bacteria, as far as known. They exist universally, in the atmosphere high or low, in waters shallow or deep, in vegetables and in animals. They present no special peculiarities to designate disease. Those found in the tongue-scrapings of healthy persons cannot be distinguished from others existing in the blood and tissues of the victims to zymotic disorders.

Professor Gradle says: "When we experiment with an isolated disease-producing germ, it causes always one and the same affection, if it takes hold at all." Has the doctor ever succeeded in obtaining any such remarkable results with isolated germs? If so, the problem is solved.

As regards Pasteur's observations, Professor Gradle is not so sanguine as some others. He remarks that "Pasteur's own account" of the results of some of his experiments are "dazzling. But a repetition of his experiments in other countries, by his own assistants, has been less conclusive. In Hungary the immunity obtained by vaccination" (*i.e.*, against anthrax) "was not absolute, while the protective vaccination itself destroyed some fourteen per cent. of the herds."

"Yet, though much of the enthusiasm generated by Pasteur's researches may proceed further than the facts warrant, he has at least opened a new path which promises to lead to results of the highest importance to mankind." Let us trust that such may be the case. Thus far, however, it does not seem that Pasteur has demonstrated anything more *as to what are germs*, than did Jenner, the practical results of whose investigations required no theory to substantiate them.

In the second article referred to, Dr. King attempts to prove that mosquitoes are the chosen carriers of the malarial germs, and insert them into the human system. He remarks: "Viewed in the light of our modern 'germ theory' of disease, the punctures of proboscidian insects, like those of Pasteur's needles, deserve consideration as probable means by which bacteria and other germs may be inoculated into human bodies so as to infect the blood and give rise to specific fevers." Here, in the same way as Dr. Gradle, he speaks of "bacteria and other germs."

He goes on to say: "With our present knowledge of the 'germ theory' one would hardly dare, even once, to plunge an inoculating needle into the blood of a yellow-fever or typhus-fever patient, whether living and comatose, or recently dead, and then withdraw it and plunge it into his own blood or the blood of other persons; yet this is exactly what the mosquito is doing in nearly every yellow-fever epidemic, and what, perhaps, the flea is doing in the filthy jails and ships infested with typhus."

Now the profession are almost unanimous in rejecting the idea of personal contagion in yellow fever—so, if any germs are responsible for that disease, the mosquito

must extract them from some other source than the infected human body. It may possibly be otherwise with regard to typhus fever, which is well known to be intensely contagious. So with some other communicable diseases. Malignant pustules are occasioned by stings of flies which must have acted as vehicles for the contaminating element. A case was recorded in 1793 by Penada, an Italian physician, where a human being was seized with hydrophobia communicated by the bite of an insect. Bollinger remarks ("Ziemssen's Cyclopædia") that certain parasites, as fleas and lice, which are nourished by the dog, may transfer rabific poison to human beings and other animals by means of their blood-drawing apparatus. We can scarcely doubt that flies convey small-pox; and an apparently authentic instance of vaccination by the medium of a flea was reported in the *London Lancet*, June 22, 1872.

No one pretends that intermittent fever is contagious, although of the pernicious variety. Even the enthusiastic Tommasi Crudeli has never, so far as I am aware, entertained any such notion. But if his theory be allowed, that malaria may be transmitted from one individual to another by the injection into the latter from the former of what he terms the malarial ferment (only, however, that taken from *pernicious* cases), then it might readily be supposed that malaria could be carried from its terrestrial haunts to human beings, or from an infected person to a well one. Still, I am inclined to believe that this musical and rapacious insect, even if he invades our bed-chambers laden with the malarial ferment of Jersey (which by the way should need no coloring under the microscope), must be acquitted of any other crimes of poisoning than that of which we all have known him to be guilty. However, no one can deny that he is a pestiferous scamp.

Very respectfully yours,

CHARLES P. RUSSEL, M.D.

4 WEST 128TH STREET, NEW YORK CITY, August 25, 1883.

PRACTICE IN NORTH MEXICO.

TO THE EDITOR OF THE MEDICAL RECORD.

STR: It may not be uninteresting to my confrères to read something about medical affairs in this country, and about my professional experience during four and a half years of arduous work in the city of Monterey. The profession in this city is well represented by a number of physicians, graduates of the different medical schools of Mexico. They are generally well educated; possess a good classical education, before being admitted to the study of the profession, and a very fair theoretical knowledge. The text-books used at the medical schools are almost exclusively French works, translated into Spanish. Their practical experience they have to acquire, to a great extent, by years of practice and observation, the hospitals in the former Spanish-American colonies being far inferior to those of Europe or the larger cities of the United States, and, in consequence of this, the clinical instruction is rather limited. The Government cannot afford such large appropriations of money as are necessary to keep them in first-rate order, and it is well known that heavy expenditures are required for the proper maintenance of these important establishments, which are the pride of other civilized countries. Moreover, the old Spanish, or rather Moorish style of architecture is not adapted for hospitals, and affords but little comfort to the patients within their walls. The low floors, consequent dampness, imperfect ventilation, equally imperfect protection against the inclemency of the weather and absence of all provision for warming the rooms are certainly serious objections. Only the poorest classes therefore voluntarily resort to them. But the professional men of this country, as a rule, are highly intelligent and imbued with the earnest will and desire to continue their studies, even after they have received their degree of Doctor. They study and work assiduously, and, in this way, attain a standard of ability, which de-

serves high praise. Their gentlemanly deportment makes it an easy task to keep on friendly terms with them and to obtain even their friendly support and co-operation. I speak of Monterey only, as I have no experience concerning these matters in other parts of Mexico. The population of the north of Mexico is a mixture of Indian and Caucasian blood. Dr. Gonzales, of this city, a gentleman distinguished for his high scientific attainments, has told me that in the State of Nuevo Leon no man of pure Indian blood could be found. Within three centuries the amalgamation of the races has become complete. But the offspring of the two races represent in appearance mostly the Indian type. The excessive use of alcoholic liquors is but rarely observed. Their dress is plain, but not without taste. Their way of clothing themselves in winter is altogether insufficient. They simply wrap a blanket around themselves, but do not put on thicker underwear, and thus expose themselves to many diseases. I speak of those of the humbler walks of life, because the wealthier classes live almost in the same way as we of the more northern latitudes. It is true the winters are generally mild, yet they are sometimes sufficiently cold to require careful protection. The cities and smaller towns of Mexico are built in the old Spanish style, the houses are imperfectly ventilated, and those of the poorer classes often not ventilated at all; the floor is not or is hardly elevated above the streets and is made either of a kind of cement or of the soil stamped and beaten down, so as to make it more even and solid. When this country was settled by the Spaniards, the towns were laid out with the view of having a running stream of potable water close by, so that, in case of an attack or siege by hostile Indians, the inhabitants had that most necessary element within easy reach. In consequence of this, the site of towns and villages is frequently found in valleys, which do not present the conditions for salubrity, which are sought for in our time.

The Spanish colonists soon found out that in this country it was necessary to irrigate lands in order to insure a crop at all times, and thus, up to this date, agriculture is principally carried on on irrigable lands. It is hardly necessary to mention the well-known fact that irrigating ditches are the most fecund sources of malaria. The water runs in them for a few days; then it is directed into others, leaving the bed of these artificial rivulets exposed to the ardent rays of a Southern sun. Add to this the imperfect drainage of many yards and corrals: the fact that many houses are without privies, and the difficulty of getting rid of the offal and refuse inevitably produced by a large accumulation of human beings, and it becomes evident that the atmosphere is not always the purest, nor the conditions for salubrity the best. The climate of the north of Mexico, for the rest, is most agreeable. We do not have to endure the excessive heat in summer which prevails in Northern cities, nor the severe colds in winter. I might recapitulate in saying that the conditions for health would be very good had not man done some things to produce the contrary effect, and had left undone others of not less importance. As it is, diseases are not infrequent and the mortality is not by any means trifling. The official statement gives the latter 966 out of a population of 39,406 during the year 1880. Statistics of a later date I have not at hand. The most frequent diseases are those produced by malaria, the manifestations of which are manifold, from the simple intermittent to the formidable, pernicious, and all the different shades of remittents, for which so many names have been invented, but which I shall embrace in that class, as I wish to avoid confusion, and as my experience has taught me that the same disease may present itself, as to the outward symptoms, in a different way in different patients, and that complications occur in one case that fail to make their appearance in others. Even in different years these diseases differ in their symptoms and malignity, while the character of the remittent still cannot be denied if the proper

use of the thermometer is resorted to. The intermittents prevail nearly the whole year round; even in winter they do not cease, for the reason, probably, that if there are a few days with a temperature which hardly ever descends to the freezing-point, they are succeeded by warm days, during which we are made aware of the fact that we live in almost a tropical country. They are but rarely malignant, but most stubborn, and I have found myself repeatedly obliged to insist upon a change of residence for some time, in order to overcome their tendency to return. Masked intermittents are very frequent, such as neuralgia of one nerve or a group of nerves. I have had even some cases in which epileptiform convulsions took place, which had been treated already as cases of real epilepsy. A careful examination of these cases convinced me that they were manifestations of malaria; percussion showed considerable increase in size of the spleen, and the convulsions lasted much longer than they do in epilepsy; besides, the attacks did not come on suddenly and almost without premonitory symptoms, but after a preliminary stage, with considerable gaping and stretching, pains in the limbs, etc. The use of quinine revealed the real character of the disorder, and stopped the attacks which previously had resisted the use of bromide of potassium, etc. In Texas I had the opportunity of treating a similar case before, and therefore I had no unknown enemy to combat.

It would be tedious to enumerate all the different disguises under which one meets intermittents in a Southern country. The large majority of cases yield readily to a judicious treatment; but there are always some which leave a state of marasmus behind. Undoubtedly, in many it is consequent upon imperfect alimentation, since the poor are really poor in this country; but in other cases the disease itself produces a long, protracted state of anaemia, consequent upon the extensive destruction and insufficient reproduction of the red-blood corpuscles. I have had the opportunity to examine the blood of such patients and found the white corpuscles considerably increased in number, although not by any means approaching the proportion existing in leucæmia. Twice I have had an opportunity to observe mental derangement in consequence of protracted intermittents. They both succumbed after months of suffering. I have seen so much of intermittents in Louisiana and Texas that it appeared to me strange that only here, in Monterey, I should meet with cases of this kind. The fact was known to me that mental diseases may follow in the wake of protracted intermittents from the time that I read Griesinger's classical work in 1869, but I found only here the opportunity of observing it personally. As stated above, my efforts to overcome the disease were totally in vain. The experience of Collin, according to his work on fevers, seems to have been similar to mine.

EDMUND GOLDMANN, M.D.

MONTEREY, MEXICO, August 18, 1883.

HOW AN IMPACTED PEACH-STONE WAS DISLODGED FROM THE ESOPHAGUS.—Dr. J. S. Prettyman, of Milford, Del., writes: "Was consulted August 8th, as to what should be done in the case of an old man who had swallowed (or rather half swallowed) a peach-stone, which had lodged about the middle of the cesophagus. He could swallow nothing, and the tube seemed to be completely occluded. I advised rectal injections of lobelia inflata. The consultant, Dr. J. O. Pierce, of this town, administered ounce doses of the fluid extract every fifteen minutes until three ounces were thus used. The patient then was so urgent to go to the water-closet, that he was permitted, when, under active emeto-catharsis, the stone came up and he cried out in great joy, 'Doctor, I have got it.' The stone was a very large one and was so tightly packed in the tube that it would have been impossible to force it down without serious injury. No other apparent effect followed the use of the medicine."

New Instruments.

AN IMPROVEMENT IN CLINICAL THERMOMETERS.

By W. R. LEONARD, M.D.,

NEW YORK.

THE accompanying cut shows a registering indestructible magnified index clinical thermometer. It is similar in construction to one described by me in THE MEDICAL RECORD of August 24, 1878: "The contraction of the bore of this thermometer is so extremely minute as to obviate the necessity for any air-speck whatever, and then no possible destruction of the index can take place, as an index is formed at every observation by this peculiar construction itself cutting off the entire column above it from the bulb portion below it. Thus we may, if we choose (no necessity exists for so doing), shake the entire column (index included) into the bulb and every time we warm the bulb a new index is formed for us by the contraction itself." The improvement that I desire to draw attention to in this thermometer is the etching of the observatory corrections in combination with the scale upon the stem. When thermometers are examined by comparison with a standard instrument it is almost invariably the case that some slight errors are found to exist in the scale, and these errors are set down on a certificate which is supplied with the thermometer, and which is numbered and marked in accordance with the numbers and marks on the thermometer, to insure identity therewith. Now, when the thermometer is used and an exact reading is desired, a certificate or a copy thereof has to be consulted and the errors added to or subtracted from the observed scale reading. This is a troublesome operation, as it involves reference to the certificate of correction, which possibly may not at the time be within reach or may be lost. To obviate this difficulty Mr. James J. Hicks of London, England, has patented the device of etching or otherwise marking the errors on the thermometer-tube itself, as shown by the accompanying cut at *a, a, a, a*. The corrections as shown in the drawing are 94.0, 100.4, 105.0, 110.0. In this case this thermometer may be called absolutely correct as it only varies $+ \frac{1}{10}^{\circ}$ at 110 and this verification is from the Kew Observatory.

In this instrument the correction is in the shape of an addition, but in some cases they will be in the form of subtractions, when the sign minus is employed. The number and monogram or other sign of any examination office at which the thermometer has been compared with the standard instrument may be applied to the thermometer. By these means the thermometer carries with it the corrections found to be necessary, thereby greatly enhancing its utility, as the correct reading can be at once obtained by reference to the thermometer alone. These thermometers are manufactured by Shepard & Dudley, New York.

THE INCURABILITY OF CONGENITAL COLOR-BLINDNESS.—Referring to an editorial on the subject of color-blindness in THE RECORD of August 11th, Dr. B. Joy Jeffries writes, calling attention to the fact that it is almost universally conceded by ophthalmologists and experts that congenital color-blindness is incurable. He refers to the contrary view held by Favre of Lyons, France. Dr. Jeffries agrees in urging the value of educating the color-sense among the children of public schools.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 1 to September 8, 1883.

SHUFELDT, ROBERT W., Captain and Assistant-Surgeon. Granted leave of absence for three months on surgeon's certificate of disability, with permission to leave the Department of the South. S. O. 204, par. 3, A. G. O., September 5, 1883.

WAKEMAN, W. J., First Lieutenant and Assistant Surgeon. Assigned to temporary duty at Fort Sidney, Nebraska. S. O. 92, par. 2, Department of the Platte, August 28, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending September 8, 1883.

DIEHL, OLIVER, Passed Assistant Surgeon. Detached from the Naval Academy and ordered to the U. S. S. Quinnebaug, European Station, per steamer of 15th ult.

ANDERSON, FRANK, Passed Assistant Surgeon. Detached from the U. S. S. Quinnebaug, on reporting of his relief, and granted leave of absence for three months.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending September 11, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
September 4, 1883.....	0	67	32	8	19	27	0	0
September 11, 1883.....	0	83	36	3	60	21	0	0
<i>Deaths.</i>								
September 4, 1883.....	1	24	2	8	1	21	0	0
September 11, 1883.....	0	27	7	2	6	15	0	0

THE LITERARY STATUS OF THE BOHEMIAN NATION.—Dr. N. Weidenthal, of Cleveland, O., writes: "In a recent issue you quote from a letter written by Dr. Councilman, of Baltimore, in which he makes a rather sweeping statement regarding the scientific and literary status of the Bohemian nation. If the doctor were a trifle better informed on this subject he would certainly modify the statement referred to. He is evidently not aware that Rokitsansky and Skoda, whose names will always occupy an important place in the history of medicine, were Bohemians; that Oppolzer, one of the greatest teachers and clinicians of his day, was a native of the same country. Professor Arlt, the distinguished eye specialist, of Vienna, Professor Albert, who was recently called to the chair of surgery at the same university, and Professor Czerny, of Heidelberg, are all Bohemians. Professor Bamberger, of Vienna, is a native of Prague, but perhaps should not be included in this list, as I believe he is not a Czech, but a German Bohemian. Professor Seegen, one of the leading authorities of the present day on balneology, is also a native of that city. I will not touch upon the non-medical side of the question, as that is of less interest to our profession. In medicine alone I might have given a longer array of names, but have deemed it sufficient to give a few which have acquired a

world-wide celebrity. It would surely be unreasonable to expect a small country like Bohemia to produce as large a number of illustrious men in any department of science or letters as countries with ten times its population. While I do not sympathize with the Czechs in their persecution of their German fellow-citizens, and consider the division of the old university of Prague to be in many respects an unfortunate occurrence, I do not like to see injustice done to any nation."

DR. ABERNETHY AND THE LATE GENERAL DIX.—In the biography of the late General Dix, written by his son, Morgan Dix, which has just appeared, is an account of an interview with the celebrated Dr. Abernethy. It will interest our readers especially, since it is known that the wisdom of the physician's advice carried General Dix from dyspeptic youth into eighty years of robust life. General Dix gives the account himself: "He received me with great civility, heard a few words of the story, and cut me short as follows: 'Sir, you are pretty far gone, and the wonder is you are not gone entirely. If you had consulted common sense instead of the medical faculty you could probably have been well years ago. I can say nothing to you excepting this: You must take regular exercise, as much as you can bear without fatigue, as little medicine as possible, of the simplest kind, and this only when absolutely necessary, and a moderate quantity of plain food, of the quality which you find by experience best to agree with you. No man, not even a physician, can prescribe diet for another. "A stomach is a stomach;" and it is impossible for any one to reason with safety from his own to that of any other person. There are a few general rules which any man of common sense may learn in a week—such as this: That rich food, high seasoning, etc., are injurious. I can say no more to you, sir; you must go and cure yourself."

A NEW METHOD OF DIAGNOSING CANCER.—In the *Journal de Medicine*, of Brussels, Dr. W. Rommelaère publishes a series of clinical observations illustrating a new fact in the pathology of cancer. He finds (in thirty-four cases) that in persons subject to cancer the amount of urea daily eliminated progressively diminishes until it is below twelve grammes. By studying the urea eliminated in cases, for example, where doubt exists between gastric ulcer and cancer, a diagnosis can be made. In twelve cases of gastric ulcer the daily urea elimination was about twenty-five grammes.

A NAIL EMBEDDED IN THE BRAIN.—In an autopsy on a patient dying in one of the Vienna hospitals, there was found in his brain an iron nail covered with rust, which to all appearances must have been there since early childhood. The man was about forty-five years of age, a bookbinder, and always passed for intelligent. Negative popular evidence, however, is of but little value. The man, at regular intervals, had epileptic attacks, and post-epileptic mental phenomena while in the hospital.—*Medical Press and Circular*.

DANGER LURKING IN SODA WATER.—The public analysts of Montreal and Toronto, Drs. Edwards and Ellis, have been examining samples of soda water, and report that in the majority of cases lead and sometimes copper is present. Dr. Edwards examined twelve samples purchased in Montreal and found lead or copper in ten of them. Five contained both lead and copper, and five contained lead only. In some samples only "traces" of the metals were found, while in others the water was "largely impregnated" with one or both of the metals. Dr. Ellis in twelve samples of Toronto soda water found only three which were free from lead. No mention is made of the presence of copper. The quantity of lead varied from .07 of a grain to .5 of a grain to the gallon, the average of nine samples being .32 of a grain. All of the above samples were taken from fountain cisterns, bottled soda water being invariably found free from metallic impurities.—*Sanitary Engineer*.

A FORMULA FOR USE IN IRREGULAR HEART ACTION.—In a discussion upon heart disease before the Boston Society for Medical Improvement, Prof. Bowditch said that he had found the following formula of great service in relieving even the most serious cardiac affections. He had used it for the last twenty-five years:

R. Pulv. digitalis gr. x.
 Pulv. colchici sem. gr. xx.
 Sodii bicarbonatis gr. xxx.

M. et div. in pil. No. 20.

These are to be taken three or four times daily at first; subsequently to be reduced until only one is taken at bedtime; the treatment to be continued for three to nine months.—*Boston Medical and Surgical Journal*.

THE POLLUTION OF WATER AT SUMMER RESORTS.—The Albany *Argus* reports the prosecution of F. G. Crosby, proprietor of the Crosby Side Hotel, Lake George, for draining the sewage from his premises into the lake. Suits were brought against him under a recent law which forbids, under penalty of \$300 for each offence, depositing or allowing to flow into Lake George any sewage or other polluting matters. The complainants withdrew the prosecution upon Mr. Crosby's agreeing to tear up the drains in their presence, which he is said to have done. Complaints of a similar nature have been heard from other quarters, notably from tourists in the Catskills.

DANGEROUS SUGAR OF MILK.—The American Institute of Homœopathy is becoming alarmed because of impurities discovered in sugar of milk. At its last meeting it resolved that any sample of sac. lac. yielding a residuum, after incineration, of more than $1\frac{1}{2}$ milligramme to each 10 grammes should be considered unfit for homœopathic use. This is right. Any impurities existing in a greater proportion than 15 to 100,000 must be exceedingly dangerous, if not absolutely fatal.

TREATMENT OF LICHEN RUBER BY UNNA'S OINTMENT.—Dr. Bockhart reports the cure of a case of lichen ruber in three weeks by the use of Unna's ointment. This is composed of one part corrosive sublimate, twenty parts carbolic acid, and five hundred parts diachylon ointment.—*Centralbl. für Chirurgie*, August 11, 1883.

MORE TROUBLE IN THE LONDON HOSPITALS.—For some time past there have been heard smothered complaints of the autocratic government insisted on by the matron of the King's College Hospital, and her aggressive attitude is said to have caused much justifiable discontent among students and staff. At length, however, the resignation of the matron was insisted on, and, after prolonged refusal, received. All of the head nurses, who sympathized with the matron in her opposition to the medical staff of the hospital, deserted their posts and left the building as soon as the fact of the matron's resignation was announced. In commenting on this occurrence, the *Medical Press and Circular* says: "That the lady would cling to her position as long as possible is to be expected; but what is really incomprehensible is that her subordinates should so far forget the traditions of charity and duty as to make the forced resignation of their principal an excuse for their own withdrawal from the wards without previously giving notice of the intention. All honor, be it added, to the nurses who, notwithstanding the absence of pretensions claimed by 'lady' nurses, remained with true womanly pity at their posts beside the beds of suffering patients, the while their cultivated 'superiors' followed in the wake of the indignant matron. Spite of the temporary inconvenience, the authorities of King's may congratulate themselves on a good riddance of women who could be guilty of so grave a dereliction of duty."

A NEW JOURNAL IN MEXICO.—A new recruit in the ranks of medical journalism has appeared in Mexico under the title of the *Revista Médico-Quirúrgica*. It is to be

published three times a month, and its first issue bears date of August 10th. In its English prospectus it claims to be "the first publication of its kind in the Republic of Mexico which has such a broad spread circulation so much in the country as abroad." It is to consist mainly of selections from foreign journals, and its first issue contains a number of good abstracts, chiefly from French and German sources. The editors are Drs. V. Blay, T. Noriega and J. Robles. We welcome our young contemporary and wish it a long and prosperous life.

REPORT OF A FATAL CASE OF INTESTINAL OBSTRUCTION FOLLOWING PERITONITIS.—Dr. Edgar A. Mearns, sends us the history of a case of the above character. "The patient, a young man aged nineteen, had had general peritonitis four years before. Since then he had suffered from occasional attacks of abdominal pain and constipation. The last and fatal attack came on July 30th and continued eight days. He was obstinately constipated. Large doses of castor oil, combined with copious rectal injections were given. There was no fever nor tympanites and no great pain. Vomiting was present, and on the fifth day it became stercoraceous. On the sixth day an injection of warm water and oil was passed high up into the large intestine. It brought away hardened feces. The vomiting ceased temporarily and it seemed that the obstruction had been overcome. Next day vomiting returned, however, and the patient died from exhaustion. An autopsy revealed the intestines matted together by the old peritonitis. The site of the obstruction was a tangle of united loops of intestine in the small gut, about the middle of the ileum. The vitality of this portion of the intestine was destroyed before death; and the loops were so tightly bound together by strong fibrous bands that the gut was perforated at each attempt to separate the coils by the most careful dissection. The gangrenous condition was produced by pressure in one of the loops, which was greatly dilated and hypertrophied by partial closure of the gut at the point of union of the loops of intestine. There was an accumulation of feces in one of them, the outlet of which was stenosed. During the progress of this case the question of attempting to afford relief by the operation of laparotomy was discussed. The autopsy showed that laparotomy, if performed, should have been done early; and, even so, the intestines would probably have been irreparably damaged in forcing the feces past the constriction, so that the probability of success would have been slight. As the sequel proved, the condition was relieved without operation; and had relief come a little sooner, while the patient was vigorous, he might have been saved for another occasion. Dr. Henry B. Sands records in THE MEDICAL RECORD, vol. xxi., p. 429, April 22, 1882, the result of a laparotomy done upon a precisely similar case, as follows: "The patient was a man about thirty, who had suffered from acute obstruction for a week before the operation. No exact diagnosis could be made. When the abdomen was opened, the intestinal coils were found extensively adherent to one another, in consequence of former peritonitis; and a careful search failed to discover the nature or seat of the obstruction. The abdominal wound was closed, and the patient died soon afterward from exhaustion."

A REMARKABLE CASE OF COMPOUND COMMINUTED FRACTURE OF THE FRONTAL BONE, WITH RECOVERY.—Dr. L. Tibbets, of Rockford, Ill., sends us the following history. A young man, aged twenty-nine, weight one hundred and twenty-eight pounds, was working at an emery wheel, fourteen inches in diameter, and revolving three thousand times a minute, when it suddenly burst, and a fragment struck him on the left half of the frontal bone. He fell down and was unconscious and quiet for about ten minutes; then violent muscular movements appeared. The frontal bone was depressed, the brain visible and pulsating. Four persons held him while Dr. Tibbets removed eight large fragments of the bone. The patient

was then more quiet. Hemorrhage was profuse, the brain membranes, longitudinal sinus, and a branch of the middle meningeal artery being lacerated. The wound was bandaged, and the patient carried home in a hack. "On the way home," says Dr. Tibbets, "he vomited blood several times, and after arriving, I gave him chloroform to quiet him while removing other pieces. One piece of the orbital plate, also a piece of the internal angular process of the frontal bone and orbit weighed one drachm. The number of pieces removed was nineteen, weight of largest (two of same weight) was one drachm. One piece was found on the opposite side of the shop, forty feet from where he stood. The combined weight of all the pieces found and removed was five drachms twenty-five grains. Hemorrhage was controlled by twisting the meningeal branch, and powdered persulphate of iron applied to the brain surface where the vessels were torn, and the wound left open until all oozing stopped, which was three hours. At two places on the left lobe, anterior, there were seen protrusions of brain matter about three-eighths of an inch in diameter. The wound was crucial shaped, extending from the root of the nose toward the middle of the left frontal bone. The flaps of skin were drawn together and a rubber drainage-tube inserted. Fluid extract of ergot $\frac{3}{4}$ j., and codeia, $\frac{1}{4}$ gr., were ordered every three hours. Some hours later he became conscious and would answer questions. Slept well that night. Next morning he could speak, take nourishment, and sit up. Temperature normal. Carbolyzed cloths were kept upon the wound. By the fifth day he was able to sit up half the time in a chair. At no time after the injury did he complain of any pain. The highest point of temperature reached was 102° , and this only for one or two days. For three weeks after injury he complained of seeing double. Though after this, his sight became normal and mind clear. I gave him examples of figures to add, columns five figures in length and nine in number, to test his memory and condition of mind. He added these readily and correctly. He sat up most of the time. In two months he walked over a mile. He had then been keeping books for the company for three weeks. I tested his sight, and found in each eye vision normal. He recently moved to Oneida, N. Y. Before leaving was able to transact business, as before injury. There was left a depression in forehead, when the bone was taken out, but, on pressure, it seemed quite hard. I have seen reported but one case similar to this, in 'Erichsen's Surgery,' page 287, when there was a comminuted fracture of frontal bone, where there were twelve pieces of bone; patient died on the ninth day. These recoveries are considered very doubtful. I have not seen, or been able to find a case reported, parallel with this, both for extent of injury and perfect recovery."

THE NERVE-CENTRES FOR UTERINE CONTRACTIONS.—Dr. Dembo claims to have discovered the ganglia concerned in the production of contractions of the uterus. He says they are situated in the anterior wall of the vagina, and are independent of the spinal cord.—*Centralbl. f. Gynäköl*, August 11, 1883.

THE USE OF ATROPINE AND MORPHINE BEFORE ANÆSTHESIA.—Dr. Aubert, of Lyons, lately forwarded a paper to the Biological Society of Paris on the Advantages of Combining Atropine with Morphia in Hypodermic Injections, in the following circumstances: 1. In all cases where injections of morphia are indicated, the analgesic action of the morphia being then considerably increased by the addition of atropine. 2. As an adjuvant to the anæsthesia produced by chloroform or ether. The nauseating effects of the substances are at the same time suppressed, which by the efforts of expectoration may, in syphilitic subjects, be attended with great danger to the surgeon or to his assistants. 3. The tolerance of the morphia is so increased by its association with atropine that it could be administered even a few minutes after a

meal without any fear of the supervention of vomiting. In the discussion that followed M. Poncet observed that all the means which tend to palliate the inconveniences of chloroformization have the effect of prolonging to a dangerous degree the anæsthetic sleep, which he considers undesirable, as it is preferable for the subjects operated on to recover their senses as soon as possible. Dr. Brown-Séquard then remarked that the employment of atropine has precisely for effect the diminution of the soporific action of morphia.—*Louisville Medical News*.

CONFIDENCE IN THE PROFESSION.—The following story, told in connection with a terrible outbreak of cholera on board an emigrant steamer, illustrates a remarkable degree of confidence in the profession. The deaths on board were so numerous that, for the purpose of indicating to the boatswain employed in removing the dead for burial, a cross was chalked against the berths where the corpses lay. By mistake, the fatal mark was attached to a berth where the inmate was engaged in a sound sleep. On the boatswain seizing him by the legs for removal, the intended victim called out loudly that he was not dead, but asleep—a remonstrance which drew from the old Scotch sailor the rejoinder, "Tut, tut, mon; the doctor knows better than you;" and who forthwith proceeded to endeavor to execute his commission.

TONGUE DEPRESSORS.—Dr. W. S. Gee, of Hyde Park, Ill., writes: "The article on the above heading, in a recent issue of your indispensable journal, calls to mind the statement of an old physician that 'many an instrument is uselessly modified merely for the sake of having the inventor's name attached.' This should be qualified in most cases, no doubt, but it is evident it is fitting occasionally. It has been my experience and observation with these instruments that most of them are not practically safe. I have used many different kinds and have decided on this course: For office use I have a glass rod, eight inches long and one-fourth of an inch thick with smooth rounded ends. This is easily cleansed, giving the least possible danger of transferring diseases. Is easily used, does not gag the patient, and in every way is more agreeable. When the necessity for the use of this instrument arises away from the office it is easy and fitting to call for a teaspoon, and I am sure an intelligent patient prefers this to a depressor taken from the pocket, which naturally enough excites his curiosity (silent, perhaps) to know when and where it was used last. If an examination of the throat with the laryngoscope is desired, Sass' is a useful one. A little more practical simplicity in our instrument makers is desirable."

A LARGE FAMILY.—The Madrid *Estafette* states that a Spanish gentleman, Señor Lucas Nequeiras Saez, who emigrated from his native land to America seventy years ago, recently returned to Spain in a steamer of his own, and brought with him the whole of his family, which consists of no fewer than 197 souls, sons-in-law and daughters-in-law not included. Señor Saez has been three times married. His first wife had 11 children at 7 births, his second had 19 children at 13 births, and his third had 7 children at 6 births. The youngest of this family of 37 is aged nineteen; the eldest, who is seventy, has 17 children, of whom the first-born is forty-seven. Of Señor Saez's 23 sons, all of whom are living, 13 are married, 6 are unmarried, and 4 are widowers; and of his surviving daughters, 9 are married. The granddaughters number 34, and of these 22 are married, 9 are unmarried, and 3 are widows; and of the 45 grandsons, 23 are married, 17 are unmarried, and 4 are widowers. There are also 45 great-granddaughters, and 39 great-grandsons, of whom 3 are married. Señor Saez has never tasted wine or any alcoholic liquor, and lives chiefly upon a vegetable diet, with but little salt. In spite of his ninety-three years, he is still hale and hearty, and makes a point of walking briskly for at least three hours every day.

CONGESTIVE INDIGESTION.

By J. MILNER FOTHERGILL, M.D.,

LONDON, ENGLAND.

ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THERE are two conditions where indigestion is due to vascular congestion: one acute, the other chronic.

Acute congestive indigestion is often an alarming condition; so much so that death from exhaustion is imminent in many cases. When it is due to an irritant poison, death often is the result; but cases of irritant poisoning will not be included in this sketch, though the treatment here given applies after the specified measures for the particular poison have been adopted. The main indications of acute congestive indigestion are vomiting (especially when anything is taken into the stomach), and a red irritable tongue. There is usually a good deal of excitement present, though this may be masked by the exhaustion which is soon induced. In consequence of the rejection of all food, including liquid matters, the fauces are dry, and much thirst is experienced. The consequence is the patient craves for fluids and swallows them eagerly, with the result of their speedy rejection by the irritable stomach. The condition is one which requires a very steady hand on the reins, as well as considerable professional knowledge, for its successful management.

In the first place it is well to make sure that the case is not one of reflex vomiting from some irritation in the pelvis, as a pregnant womb, or an irritable ovary, especially if the patient be a young woman. Reflex vomiting does not carry with it any rise of temperature, and, what is certainly equally important, does not alter the aspect of the tongue. When vomiting occurs with a clean normal tongue, it is clearly not connected with primary disturbance in the alimentary canal. This is a very important matter, and forms a trustworthy broad guide in practice to the line of investigation to be taken in order to clear up the nature of the case; and here correct diagnosis gives the clue to the appropriate measures to be adopted. Still, practically, there ought to be no difficulty in making the diagnosis betwixt reflex vomiting and congestive indigestion. Taking the tongue as the guide, the mucous lining of the stomach is vascular, and that organ, bodily, irritable, and ready to resent the intrusion of any fluid. The thirsty sufferer gulps down a quantity of fluid, only for it to return almost as soon as down. The stomach is tender to the touch; and is contracted—in all probability, for exact physical examination is impracticable. The bowels are constipated because they receive little or nothing from the stomach. Diarrhea may be present as a troublesome complication.

In such a condition the great problem to be solved is how to feed the patient? It is quite clear that exhaustion is not far distant; and that the measures taken shall be prompt and effective. No medicine is retained, so it is impossible to soothe the stomach by opiates given internally. Of old there were two courses open: (1) to raise a blister quickly over the stomach and dust the raw surface with morphia; and (2) to throw up a starch enema containing a dram of laudanum. Now, fortunately, the hypodermic syringe supplies us with a ready means of bringing the system, and with it the stomach, under the influence of opium or its derivatives.

And in employing the syringe a cautious boldness is indicated. A full dose should be given at once; timidity suggests small doses repeated at short intervals. My own preferences are in favor of a dose which will probably procure sleep. After a few hours of sleep the stomach will be found much less irritable. At the same time an enema of pancreatized milk gruel, or of baked flour and peptonized beef-tea, might be administered when the patient is beginning to come under the influence of the opiate. If this can be given without much disturbance, and the enema is retained during the sleep, the patient will awaken considerably refreshed.

If necessary both manœuvres may be repeated. If the thirst be great, then chips of ice may be given to the patient to suck, and as the cool moisture passes over the fevered fauces relief is given. The room should be darkened, and the nurses should be as quiet as mice in their movements and sparing of speech; while whispering should be absolutely forbidden, for it is far more disturbing than speech. Watchful, deft-handed attendants are desirable, who can place a cloth moistened with vinegar or salvolatile, as circumstances require, over the aching brow without any unnecessary disturbance of the patient.

Such should be the line of treatment in what may be called critical states. As soon as the stomach is somewhat quieted down it is well to give a small opium pill. This might consist of one grain of opium in powder made up with half a grain of extract of opium. Such a trifle will scarcely offend the stomach, and is retained. If, however, the presence of even this trifle is resented, and the pill is thrown up, then make a lesser pill still, say one-fourth of a grain of morphia, by preference the muriate, with half a grain of the extract of opium. If the stomach have been at all soothed by the hypodermic injections, probably this will be retained. If not, administer an hypodermic injection, and when the patient is coming under the influence of it, try the little morphia pill again. If it is retained, then the local sedative action of the opium is secured, and this once achieved the after-treatment of the case becomes simple. It is in the treatment at this critical stage that the knowledge, the patience, and the resources of the physician are most taxed; when the patient is in much suffering, and perhaps thereby rendered unreasonable; while the relatives are almost beside themselves with apprehension on the one hand, and eagerness to be of some service on the other. Once the little mite of a pill is kept down, then the corner is turned in all probability.

The line on which the physician must proceed is distinct enough and intelligible enough; but it is easier described than followed out in practice. The patient craves for drink; the friends are anxious to give it; but the contracted, irritable stomach resents the presence of any bulk of anything fluid or other, and ejects it; the attempt having only further irritated the stomach, while no good end has been served.

Once having placed the pill successfully in the stomach, where it has remained, then the case moves on. The ice may now have a food-value attached to it, by freezing milk and giving a chip from time to time to be sucked. Or some rose-water containing some sugar, or other sweet and palatable fluid may be frozen and chips be given to the patient from time to time. But this must be done cautiously and no acid enter into the composition of the frozen fluid on any account. Acids, even

vegetable acids, though agreeable to the palate, are injurious to the irritated mucous membrane.

How long a hypodermic injection and a nutritive enema must be continued, at bedtime, mainly depends upon the circumstances of each case. When small sips of milk can be retained, and frequently taken, then the necessity for these measures is materially reduced. But the quantity taken at once must be kept very small; if vomiting be again set up, the steps must be cautiously retraced. The tiny opiate may be continued at bedtime for some time, even after a mixture is practicable. Bismuth with an alkali and a little solution of morphia, or some plain laudanum, or other galenical preparation, may be given twice or three times a day, and soothes the mucous membrane famously. Such is the line to be pursued patiently and cautiously; whether there be simple gastric disorder, or the condition come on in the course of some other malady, as typhoid fever. One great matter scarcely enough thought of is the amount of curdling of the milk which may go on in the stomach. If too firm a curd be formed it does not properly dissolve again, but remains a source of irritation to the stomach. When vomited the condition of matters is readily revealed. But if the curd pass downward it may escape notice. Should masses of hard curd be found in the motions, the milk must be mixed with some farina and a fixed alkali, like prepared chalk or calcined magnesia, be added, which will prevent the formation of too firm curd. When the firm curd is formed, it involves not only the wasting of the milk as a food, the patient being no better for it, but the greater matter, viz., irritation of the bowels till diarrhoea may be set up, or even some muco-enteritis. Frequently, indeed, is it necessary to give a more potent alkali than lime-water with milk when too firm curdling is found, and then the chalk or light magnesia can be stirred into the milk with a little biscuit powder if desirable, just before the patient drinks it.

But whatever is given let it be in small quantity at once, else the irritable, contracted stomach will certainly reject it.

An acute condition of congestive indigestion is found along with alcoholic excess under two totally different circumstances. First, after a debauch where the alcohol has been so concentrated that the mucous lining of the stomach is congested, almost inflamed. There is thirst and fever, and the sufferer drinks greedily, the fluid being retained only a very brief time. Then it is well to give the patient milk and soda-water, the carbonic acid gas acting as a local sedative. The little mite of a pill (mentioned above) may be given also, twice or three times in the twenty-four hours. As to how far the patient may have some effervescing beverage containing alcohol is a matter to be determined betwixt the patient and the physician in each case.

Then, at other times the case is rather as follows: The patient is acutely ill and is being plied freely with brandy and water, or its alcoholic equivalent, under the impression that exhaustion will thus be averted. But the tongue gets redder and the stomach more irritable and the bowels more tympanitic, until it is only too clear that the alcohol is producing acute congestion. Then the alcohol must be withdrawn, however strongly the general condition may seem to require it, for the gas evolved in the stomach and bowels presses up the diaphragm and not only prevents its descent, but the pressure embarrasses the heart. Indeed, the elastic pressure of the gas impedes both the respiration and the circulation, and consequently the alcohol is doing more harm than its stimulant effect counterbalances. Unless the alcohol be promptly stopped, under these circumstances the patient will probably sink. If there be no other remedy feasible the alcohol may be administered per rectum. (Probably the subcutaneous injection of strychnine would maintain the action of the centres of the circulation and the respiration as effectually as alcohol could do.) This last aspect of the relations of alcohol, given

medicinally, to acute gastric congestion is often overlooked; yet the condition is not so very rare! So much then for acute congestive indigestion.

Chronic congestive indigestion is found with all maladies which impede the blood-flow in the portal circulation. Consequently it is found with failure of the right ventricle, whether this be consequent upon a mitral lesion, leading to pulmonary congestion, or there is present some condition affecting the lungs generally, as emphysema or cirrhosis. Or it may be some hepatic condition which gives rise to the portal congestion, as cirrhosis or cancer. The effect is to produce fulness of the gastric venules, with a catarrhal condition of the stomach while the gastric juice is diluted, and therefore diminished in potency. The prominent sensation complained of by the patient is "sense of fulness," even when the stomach is empty. Why this sensation should be found with this fulness of the gastric veins, it is not easy to say, but the fact remains. The difficulty of digestion in all such cases is very great, and the management of the condition no easy matter. The impeded blood-flow affects the arteriales and the gastric fluid is sparingly formed, and is of enfeebled energy, being diluted from the venous fulness, and effusion resulting therefrom. Yet the nutrition of the heart and the respiratory muscles must be maintained, else it is clear the patient will soon sink. The food must consist of the blandest and most easily digested material, containing no solid materials, which would only be covered with a layer of mucus as it is rolled over and over by the movements of the stomach.

Milk and seltzer water, beef-tea or chicken broth with some biscuit powder, must form the dietary if the case is very serious. If the dyspepsia be slighter, then some milk gruel, milk puddings (made without an egg), or even white boiled fish may be sufficient. As improvement is made, the dietary may be made even more substantial, and nice thin sandwiches made with potted meat, stewed fruit and cream may be permitted. As to alcoholic fluids, if they agree and help the patient to eat and digest, there is no valid reason why they may not be allowed. Then as to direct medical treatment; at times some astringent, as compound kino powder, may be indicated by a catarrhal condition.

But the treatment *par excellence* is the relief of the venous congestion; and the stomach is needed for a good deal of medicine, as well as food. There is the filling of the arteries and the emptying of the veins, the improvement of the arterial blood-pressure, for which digitalis and its allies are available. The increase in the blood-pressure produces a freer flow of urine, and that is good—as well as a good indication of the medicine is acting well. As in all cases of right-side embarrassment the respiration is impeded, it is well to add some respiratory stimulant, as strychnia for instance. Such respiratory stimulant usually adds much to the efficiency of the stimulant to the circulation; and digitalis is rarely, if ever, indicated where the addition of strychnia is not also suggested, and the combination gives the best possible results. In some cases too, where digitalis does not suit the patient, the addition of strychnia will at once produce good effects. (This is a matter of such importance in practice, in my experience, that I beg the reader to give the subject his best attention. Some time ago I was called to a case in the country, where digitalis, potash, and scopolarium with elaterium had been given, with the result that the dropsy was rising, in a case of mitral stenosis. It was quickly apparent that the respiration rather than the heart was failing, and ammonia with strychnia was substituted for the potash, with almost magical effect; and the new direction has been maintained. All that has been said about the venous congestion, of right heart embarrassment, and its effects upon the gastric venules, was well pronounced in the case.)

By such means, together with a smart cathartic once or twice a week, which drains so much water away by the bowel, the condition of venous congestion is greatly re-

lieved. And a smart cathartic means a full dose of the agent adopted, which may be a pill of one-sixth of a grain of elaterium, or a powder of one-tenth of a grain of elaterium with ten grains of compound scammony powder. The good of such a full dose is to secure its acting freely. This is what Dr. King Chambers says: "In all forms of dropsy the effect which you desire to produce by remedies is strikingly dependent on the condition of the alimentary canal. Where the portal system is congested, I have given that strongest of purgatives, elaterium, in doses gradually augmented up to three grains, without any of the vigorous hydragogue action naturally following, and then, by applying a few leeches to the anus, so as to disgorge the abdominal veins, half a grain has produced excessive purgation with reduction of the dropsy." The reader may think the doses of elaterium here spoken of as certainly heroic. But when a patient is water-logged in venous fulness, the effect of a brisk cathartic is very different from what it is on a healthy person. There may be some risk of exhaustion or syncope at the time of the catharsis to be guarded against by free recourse to stimulants, if necessary, but the immediate after-effect is a sense of distinct relief.

Stimulants to the circulation, with respiratory stimulants, improve the circulation, while free catharsis relieves the venous fulness; these are the great measures to be adopted in chronic gastric congestion leading to indigestion—*i.e.*, measures addressed to the circulation. Then the dietary must be adapted to the state of the digestion, and some artificial pepsin may be very useful to help the dilute, feeble natural pepsin in the work of digestion.

Gastric catarrh is not, however, always the effect of venous congestion, and then astringents are clearly indicated. But when it is the outcome of obstruction to the circulation the cardinal measure to be adopted is the improvement of the circulation, upon which the gastric catarrh is relieved.

CIRCULAR RESECTION OF THE INTESTINE, AND CONSEQUENT UNITING BY SUTURE, WITH THE HIS- TORY OF TWO CASES.

By EDWARD J. ILL, M.D.,

NEWARK, N. J.

ABDOMINAL surgery has within the past ten or fifteen years received the attention of the most eminent surgeons, and nevertheless many points are still so unsettled that every contribution, be it ever so slight, should be received by the profession with interest.

Especially is this the case in operations upon the stomach and intestines, and every experience ought to be carefully recorded, so that deduction may be made and guide us in further researches. These operations have many enemies, and the results of those who operate will be watched with the greatest interest, and probably closely criticised.

It will be the province of this paper to speak especially of circular resections of the intestines for cases of gangrene from strangulated hernia, not including wounds of the intestines produced by accident, or where during the progress of other abdominal operations it has become necessary to remove a piece of intestine, nor the wonderful achievements gained from resections of the pylorus.

Randohr removed a piece of intestine (small intestine probably) two feet long, and united the ends by suture, in a case of gangrene from hernia, as early as 1727, and with good result. This was followed ten times, up to 1836, by French, English, and German surgeons, with the following results: five were cured completely, two had an artificial anus, and three died. From 1836 to 1875 it seems nothing was done in this line, and it is due to Langenbeck (1875), Kuester (1877), and Czerny (1878), to have revived this important operation. Since then the operation has been done thirty-four times, with

twenty deaths, making in all forty-four operations and twenty-three deaths. This, after a collection of cases by Mandelung and Rydygier, in November, 1881. Since then I have found notes of one case by Rydygier (*Berlin. Klin. Wochenschrift*, September, 1882), which was successful, and another by Dr. Q. A. Anan, in December, 1881 (*Schmidt's Jahrbücher*, 1881, p. 286), which was fatal.

A third case was reported by Dr. H. O. Marcey, of Boston, Mass., who operated in 1881, and to whom I am much indebted for the notes of his case. The case proved fatal.

The cases reported by Dr. G. D. Beebe, of Chicago; R. S. Sutton, of Pittsburg, Pa., and Wm. A. Byrd, of Quincy, Ill., do not properly belong to the scope of this paper, though the results, especially of the latter two, are very gratifying.

To this I should add two cases of my own, of which one recovered and the other was fatal. This makes a grand total of forty-nine operations and twenty-three deaths, or forty-nine per cent.

CASE I.—Strangulated hernia, seven days' standing, resection of large intestine, fecal fistula, cured. Mrs. S. M—, born in Russia, twenty-four years of age, widow, and mother of two children, aged seven and five respectively. Shortly after the birth of her first child she noticed a lump in the left groin, which she never entirely lost.

On April 2, 1883, she suddenly felt a pain in the left inguinal region, for which she sought medical advice.

On the fifth day thereafter, late in the evening, she was taken to the German Hospital of this city, where I found her in my ward on the next morning. The patient had a large swelling in the left groin, painful on pressure, of bluish-red discoloration, fluctuating, no impulse during cough, and no tympanitic resonance on percussion. She has not had a movement from the bowel since April 2d, and vomited mucus on the morning I saw her. She seemed very much depressed mentally. The pulse was 120, and temperature 100°. Alvine injections brought away very little feces. Hot poultices were applied, and the house physician directed to get some of the history, just detailed, from the patient's friends, as it was difficult to understand her. The patient remained quite comfortable until the evening, when she showed signs of prostration, and a hypodermic syringe brought away some bad-smelling reddish serum. I decided to operate the next morning by opening the tumor and finding its contents.

April 9th—the patient was etherized, and after incising the skin the subcutaneous tissue was found infiltrated with a yellowish-gray matter of slightly fecal odor. Very soon I entered the hernial sac from which the fecal odor was penetrant. A piece of grayish-looking gangrenous large intestine, which was perforated, was found. It was a femoral hernia and the stricture so severe, that it was difficult to introduce even the tip of the finger. After dilating and cutting the stricture somewhat it was found impossible to draw the gut down. I decided to do laparotomy, take the gut from its confined position, cut the diseased portion off, and unite the ends by suture. I had been fully prepared for this both by getting all things ready for this formidable operation, as well as by making myself familiar with its technicalities by operating successfully upon lower animals.

The wound at the hernia, the sloughing intestine, and the sac were thoroughly washed with a two and one-half per cent. solution of carbolic acid.

An incision three inches in length was now made in the median line, just as in ovariectomy. The small intestines were highly inflated and very congested, but there was no general peritonitis. The gut which entered the canal was soon found, all the firm adhesions separated with the finger, the gut withdrawn and brought out at the wound in the median line. It was found that the gangrenous part was the lower part of the descending colon, and the mesentery just implicated. The peritoneal covering of the intestine in the neighborhood of

the constriction was very much inflamed. A small opening was made into the mesentery, and two clamps were placed upon the healthy part of the gut to prevent the contents from escaping. The gut was now cut through quickly with a pair of scissors about one-half inch from the dead portion at one place, some of the constricted portion being left.

The hemorrhage was severe, and the clamps being rather in the way, they were now removed and the ends of the gut firmly held by my friend, Dr. Kornemann, to whom I am much indebted for his careful assistance in this case. Fourteen ligatures had to be applied to bleeding vessels. I had great care exercised so as not to produce any laceration of the mesentery or separation of it from the intestine, which would produce gangrene, as has been shown by the researches of Professor Mandelung in a paper read before the Tenth Congress of German Surgeons in April, 1881. I now commenced placing sutures of finest silk (which had previously been boiled in a five per cent. solution of carbolic acid) with fine, non-cutting, slightly curved needles. The first stitch was inserted into the intestine close to the meso-colon and just including this. The second stitch was placed in the same position on the other side of the gut. The next just opposite the insertion of the meso-colon, and the rest midway between the two extremes, until about thirty sutures were applied and as close to each other as possible.

The mode of inserting the sutures was such as to catch up the peritoneum and muscular coat, and not to include the mucous membrane. At the place where the tissue was inflamed the stitches tore through easily, and double thicknesses of the silk were used.

The gut was returned into the abdominal cavity after this, and the former had been thoroughly cleansed of all blood, a drainage-tube placed into the retro-uterine cul-de-sac, and the wound closed with eight deep silver wire sutures. This was covered with silk protective and carefully prepared iodoformed cotton. The lower wound was thickly covered with iodoform and cotton placed over it. Temperature after the operation was 98° ; pulse, 116; and respiration, 24. To prevent vomiting, one teaspoonful of hot water was given every fifteen minutes for twelve hours after the operation. In the evening, pulse, temperature, and respiration remained the same, but the tongue was dry and brown, skin moist, and patient complained of colic-like pains. There was slight tympanitis and occasional eructations of gas.

Hot barley-water was given during the night, and the patient remained quite comfortable.

April 10th.—At 6 A.M., eighteen hours after operation, the patient passed the first flatus, which was followed by an almost continual discharge all day. The eructations ceased and tympanitis disappeared, and there were very few colicky pains.

About 9 A.M. the dressing was changed, and about seventy-five grammes of grayish muddy-looking fluid removed from the drainage-tube. There was no unpleasant odor to this, still the tube was rinsed with a solution containing carbolic acid $\frac{1}{2}$, soda chlor. 5.0, and water 500.0, and dressing reapplied.

The lower wound was rinsed with two and one-half per cent. sol. of acid. carbol., and covered with iodoform and cotton. During the day milk and beef-soup were given in small and frequent doses. In the evening there was neither a rise in temperature, pulse, nor respiration, though the patient felt very weak, and larger doses of nourishment were given.

April 11th.—Dressing changed, and ten grammes of light straw-colored fluid removed from the drainage-tube. Gases still passed by the anus and gave no pain. The patient was nourished as during the night, and at 2 P.M., fifty hours after operation, the patient had an abundant, soft, natural-looking movement from the bowels, with but little pain. A second movement occurred two hours later, which was very painful and streaked with a little

fresh blood. A third movement followed at 6 P.M., and small doses of morphine were given to quiet the bowels.

April 12th.—The evening temperature rose to $100\frac{3}{4}^{\circ}$; pulse and respiration were the same as before.

April 13th, 9 A.M.—Patient has a desire to evacuate the bowels, and cannot be kept from straining. Dressing was changed, and still a small quantity of fluid removed from the drainage-tube. Morning and evening temperature $100\frac{1}{4}^{\circ}$.

April 14th.—Patient spent a restless night and had much straining. On changing the dressing quite a quantity of fluid feces had escaped on the left side of the tube. This was five days after the operation. Patient's tongue was very dry, as was also her skin. Temperature $100\frac{1}{4}^{\circ}$; pulse, 116; and respiration, 26. At this time I was utterly at a loss what to do about the drainage-tube; to remove it would probably allow feces to enter the abdominal cavity and kill the patient, nor was there any object in keeping it there any longer. The skin about the drainage-tube was thoroughly rinsed with two and one-half per cent. sol. of acid. carbol., and in the evening the same thing was repeated; but I was still meditating about the drainage-tube, which seemed to me a "nolle me tangere."

April 15th.—The quantity of feces which escaped this A.M. was still larger than yesterday. I had decided to introduce through the glass drainage-tube a smaller and shorter one of soft rubber. This was done without any difficulty, but a large quantity of feces followed the tube. Patient was very comfortable, and flatus were always passed per viam naturalem.

April 16th.—Dressing changed; drainage-tube removed, as it was filled with feces, and wound well rinsed with two and one-half per cent. sol. of acid. carbol.; two silver sutures removed, and iodoform dusted over the whole wound. Temperature was $101\frac{1}{2}^{\circ}$, and pulse varied between 120 and 130.

April 17th.—There was no reaction following the removal of drainage-tube. Two small abscesses formed along two silver sutures and these sutures were removed. In the evening warm water was injected into the rectum with an irrigator. After a pint had been injected the water came from the fistula.

April 18th.—The last stitches were removed to-day. Patient partakes freely of beef-soup, milk, finely chopped beef, and toasted bread. During the night patient passed several scybala per anum.

April 19th.—Patient's temperature rose to 103° without any definite cause. The fistula carefully cleansed, and again covered with iodoform. Patient again passed feces by the anus.

From April 20th to April 25th the condition remains the same, except that the temperature came down to 100° .

May 1st.—The quantity of feces from the fistula decreases as the quantity voluntarily passed by the anus increases.

May 2d.—No discharge from the fistula, and a well-formed passage by the anus.

Nothing more can be added to this already somewhat lengthy history, but that no bad symptoms followed the last date, and patient was dismissed cured entirely about fifty-one days after the operation, and remains so to this day.

CASE II.—Strangulated inguinal hernia, operation, cure; strangulation recurs, eight inches of small intestine gangrenous, resection, peritonitis, death. F. K.—, fifty-seven years of age, iron-worker, German, has suffered for four years from a right inguinal hernia, and for sixteen years from chronic gout, resulting in great deformity of hands and feet. Early in the evening of July 7, 1883, the rupture came down, and could not be reduced by the patient. He did not seek advice until July 8th, when he was sent to the German Hospital by my colleague, Dr. F. Schmascher, who requested me to operate. The patient was relieved by ordinary herni-

otomy, the sac not having been opened. The patient made a good recovery until July 20th, when, at 2 A.M., the rupture suddenly reappeared during exertion of turning in bed. Pains gradually increased. I saw him at 10 A.M. He was greatly prostrated, had a temperature of 102° , and his abdomen was tender and tympanitic. Taxis was applied without effect, and at 10 A.M. I operated to relieve the stricture. This time I was obliged to cut the sac, and, to my astonishment, I found the gut black and without the usual lustre. I cut the stricture and left the gut *in situ* to recover; if such was not the case, to remove the gangrenous portion as soon as I was prepared.

3 P.M.—The patient had been vomiting fecal matter in large quantities since the cutting of the stricture. The gut was re-examined and found to be in the same condition as in the morning, and I resolved to resect the gangrenous portion and unite the ends by suture. The gut was carefully drawn down through the inguinal canal, and eight and a half inches of small intestine removed. From the appearance of the healthy gut it was apparent that general peritonitis had already set in. The mesentery was ligated in toto, and the gut united as in the first case, except that a double row of fine silk sutures (Czerny) were used. From twenty-six to thirty interrupted sutures were used, and only three vessels ligated.

During the operation the gut became greatly distended and purple, partly from the slight constriction above and partly from the force which had to be applied in bringing the gut out to be conveniently handled. A rubber drainage-tube was inserted to the abdominal cavity and the wound treated with iodoform. Patient was given morphia soon after he came to from the anæsthesia. Temperature, 102° ; pulse, 126. He was greatly relieved from pain, vomiting of fecal matter recurred but once, eructations were frequent. He was treated the same as the foregoing case, excepting that morphia was given him for his peritonitis. During the following night patient suffered much from tympanitis and colic-like pain in the neighborhood of the wound.

July 21st.—At 7 A.M. temperature was 103° and pulse 132. Patient continued same as in the night. There was no great discharge from the drainage-tube, and brandy was ordered in large doses; ice-bags placed upon the abdomen. At 11 P.M. temperature was $105\frac{1}{2}$; the first flatus passed, tympanitis grew less, and eructations ceased. Wherever hypodermic injections of morphia were given ecchymotic spots appeared.

May 22d.—At 7 A.M. the patient suddenly got a severe watery diarrhoea, which was ejected with such force that the fluid passage reached the foot of the bed. Temperature was $105\frac{3}{4}$, pulse hardly perceptible; hands grew cold, coma set in, and death ensued at 10.30 A.M., forty-two hours after operation.

A post-mortem examination was made at 12 M. The gut was firmly united by fibrinous adhesions, and was situated in the neighborhood of the right inguinal ring. General peritonitis was present, which caused the death of the patient.

It seems to me proper to analyze these two cases, to compare with others of a similar nature and to draw deduction, which may throw light upon future cases; for I believe the operation not only justifiable, but its range of application wide, and every surgeon may be called upon to do it and without great preparations. To illustrate this I should say that in the brief time of seven years I have been called upon to operate for strangulated hernia twelve times, and three times the gut was gangrenous. Of course, there cannot be any great preparatory treatment, which is always of so great importance in capital operations, except, I should say, that all antiseptic precautions, especially about the ligatures and sutures, should carefully be observed. As to where the operation shall be done; whether the gut be dragged down through the hernial opening and there cut off, or shall laparotomy be performed?

In Case I. I was unable to drag the gut down; the tissue was so infiltrated with fecal matter that I was afraid of infection and troublesome hemorrhage should I make large incisions into Poupart's or Gimbernat's ligament.

In Case II. this could be done to some extent, but the inconvenience occasioned by operating in a small space and the congestion of the gut produced by the constriction at the opening made the operation a great deal more difficult. Section at the median line is quickly and easily done, the gut handled readily, the peritoneal cavity cleansed with perfect safety, and drainage well established if thought prudent. I shall hereafter always prefer laparotomy. Concerning the resection of the gut itself. Before the gut is cut some preventive will have to be taken to keep its contents within. Some—Billroth, Gussenbauer, and others—recommend digital compression, to which I can only agree; while others advise the use of forceps (Kocher) or clamps (Rydygier), and still others ligate with catgut or silk. I think digital compression best, because the same assistant can keep the intestines in general from prolapsing, and will also be able to adjust the two ends of the intestine.

In describing the operation in Case I., I have said that I left part of the constricted gut. I shall be careful hereafter to cut away all the diseased portions, as the sutures cannot be relied upon in cedematous and swollen tissue. The greatest care must be exercised not to strip the gut of its mesentery, as gangrene of that part of the intestine will surely follow, as was shown by Mandelung and Rydygier in their experiments upon animals. If the mesentery is gangrenous it must be removed by triangular excision, the vessels ligated, and the edges brought together by suture; if not, it may be ligated *en masse* and separated from the intestine by cutting close to the part to be removed; or else the vessels may be ligated separately. I have preferred to ligate in toto before cutting off the intestine in Case II., and found this to work admirably. The intestine must be cut across at right angles to its axis unless one severed end is smaller than the other and would therefore not adapt itself. In this case it must be cut across at an acute angle to the axis and the insertion of the mesentery, thus affording a greater circumference.

Sutures.—Concerning the material the operators differ in opinion. Czerny, Billroth, and Mandelung prefer carbolized silk, while Shede, Dittel, Riedinger, and Rydygier prefer carbolized catgut. From statistics published by Mandelung and Rydygier, there does not seem to have been any difference as to the result, which was used. There is no doubt that silk is easier handled than catgut, and does not produce any more irritation, provided it be thoroughly antiseptic. It becomes absorbed readily, although not so quickly as catgut, and would from this cause be more reliable.

How to apply the suture.—Upon this rests the success or failure of the operation to the greatest extent; it matters little, it seems to me, what material is used, as I have said before.

After section of the gut, the mucous membrane, if it protrude too much, may be cut off so as to be on the same height with the serous covering. I have not found this necessary in my two cases. To begin with, I have applied two sutures to the intestine, one on each side of the mesentery and close to the mesentery, then on the side of the intestine directly opposite to the mesentery, then stitches midway between these two extremes, and so forth until all sutures are applied. This method will most likely bring the parts best into apposition. The sutures must be applied so that it will bring serous surfaces together. This can be done by enclosing in the suture the peritoneal covering and muscular coat only.

Czerny very ingeniously has practised the method of applying a second row of sutures over the first (Etagen-naht), so as to imbed the first one between two peritoneal

surfaces, thus preventing completely the escape of intestinal contents into the cavity of the peritoneum.

Mandelung has used, with success, small plates of aseptic cartilage after the fashion of buckshot suture.

Jome Joppe, Nussbaum,¹ and Rydygier,² first apply a continual suture, and over this an interrupted one. Dr. H. O. Marcy, of Boston, has also applied a continuous suture. This certainly can be done quicker than the interrupted suture, but should one stitch tear, the whole work will have been useless.

I will not lengthen this paper by describing the different forms of invagination and following suture as was practised by Jobert and Mandelung, since it was not followed by good results.

The question naturally arises, how many patients die from a gangrenous gut due to strangulated hernia. I have taken pains to ask a number of prominent physicians in this neighborhood, to whom I am much indebted for their ready answers, what their experience was in this line. They have kindly furnished me with records of twenty-nine cases, of which twenty-five died, or eighty-six per cent.; this being an increase in deaths of thirty-seven per cent. over the operated cases, which certainly would show how justifiable the operation is, even in its infancy.

Out of the four cases which have recovered with an artificial anus, one recovered even from this spontaneously.

DOUBLE SALPINGO-OVARIOTOMY—RECOVERY.

REPORTED BY W. R. PRYOR, M.D.,

ASSISTANT GYNÆCOLOGIST TO ST. ELIZABETH'S HOSPITAL, NEW YORK.

History.—The patient is thirty-two years of age and married. She began to menstruate when sixteen years of age, and did so regularly up to the time of her marriage, ten years ago. Before and during her marital life she has suffered a good deal at each menstrual epoch. She has had two children, and two miscarriages; her last pregnancy resulting in a miscarriage about three years ago. Her present trouble dates from that time. For six weeks after this abortion she bled almost continuously, and at the same time suffered very acute pain in her pelvic organs. The symptoms were thought to be due to a laceration of the cervix uteri, which existed, and for which an operation was successfully performed by Dr. Watts. The bleeding ceased, but she remained in bed for over two months longer, with all the symptoms of severe pelvic inflammation. She improved a little, sufficiently to get up and walk about the room, but soon she had a relapse and was again confined to bed for many weeks. For the past three years this woman has continued in this way, alternately confined to bed with the most intense pelvic pain, which was relieved only by large doses of opiates; or up, scarcely able to walk, and every effort greatly increasing her suffering, she at last arrived at that point where life was made bearable by opium only; and she readily and eagerly accepted the proposition of an operation.

Examination.—The patient is thin, but in better health than we would expect to find her after hearing her history. The uterus was perfectly movable antero-posteriorly, but its mobility was very much restricted laterally, especially on the left side, in which direction it was slightly drawn. The left Fallopian tube could be distinctly felt as an enlarged and thickened cord, and most exquisitely sensitive to pressure. The ovary also of that side was very tender. There was not so much sensitiveness developed on pressure in the right ovarian region, but one could distinctly feel the ovary greatly enlarged. On examining her with Sims' speculum, we found a good deal of free pus in the vagina. This was wiped away,

and she was again examined in the dorsal position. Placing her in Sims' position again, we found that more pus had entered the vagina, but no fistulous opening could be seen. On making gentle pressure in the region of the left tube, pus was seen to ooze from the os externum in considerable quantities. As the pus was quite fluid and not mixed with tenacious mucus, and as there were no signs of metritis or endometritis, we naturally came to the conclusion that the Fallopian tubes were the seat of a purulent inflammation.

The operation was performed by Dr. W. Gill Wylie at 3.30 P.M. A Sims uterine repositr was placed into the uterus, and gentle upward pressure was made with it, thus greatly facilitating reaching the uterus and its appendages from above. The primary incision was short, not more than three inches, being more exploratory than otherwise; it was subsequently enlarged. After the skin all the tissues were divided upon a broad director, and the abdominal cavity entered to the left of the linea alba. We found the left ovary prolapsed and somewhat adherent low down to the wall of the true pelvis, with the tube firmly adherent to the ovary. The right ovary also was adherent, but the tube of that side was free. The ligatures used were of silk, and two were applied on each side of the structures to be removed. This was rendered necessary by the extent and vascularity of the adhesions. In passing the ligatures we used a full-curved round needle, about two and one-half inches long. After tying off, and removing the left ovary and tube, the stumps were held up for a few moments to make sure that no bleeding was going on, touched with Paquelin's thermo-cautery, the ligature cut short; and the stumps returned. The same method of procedure was employed with the right appendices uteri. Having removed all free blood and clots from the pelvic cavity, and again examining the stumps for bleeding, the abdominal wound was closed with silk sutures.

The following extremely useful precaution was taken in this case: As soon as the abdomen was opened several temporary silk sutures were passed through each lip of the wound, and including all the tissues from skin to peritoneum, thus preventing the stripping back of the peritoneum from the muscles when the hands are passed into the abdominal cavity. Should this accident occur it is usually impossible to prevent the sutures tearing through the peritoneum when we endeavor to close the abdominal wound. After the operation a carbolic dressing was applied. Operation completed in an hour.

First Day.—Patient slept till 7 P.M., then awoke with some abdominal pain. Pulse, 90. 9.30 P.M.: Has been asleep since 7.45. Vomits very little. Pulse, 92. 11.30 P.M.: Has slept most of the time since 9.30. Slight pain. Hiccoughs occasionally, and has a little eructation of watery material. Temperature, 99°; pulse, 94; respiration, 16–18. Sleepy. 11.45 P.M.: Increase of pain, occurring spasmodically.

Second Day.—4 A.M.: Slept steadily up to 1.30 this morning. Since then she has awakened occasionally. Temperature, 99½°; pulse, 100; respiration, 20. Complaints of thirst and slight chilliness. General condition excellent. Is quiet and mind calm, being disposed to drowsiness. 10.30 A.M.: Temperature, 100°; pulse, 92. 12 M.: Temperature, 99½°; pulse, 108; respiration, 10. 3 P.M.: Temperature, 100½°; pulse, 100. For the first time allowed her to have nourishment—koumiss in 3j. doses. 8 P.M.: Temperature, 101¼°; pulse, 118. Koumiss in 3j. doses. 10 P.M.: Temperature, 101½°. 11.30 P.M.: Temperature, 101°; pulse, 118. Since the operation fourteen ounces of urine have been drawn; she has taken ten ounces of koumiss, and has received gr. ijss. morphia, hypodermically. In the past twenty-four hours she has not vomited once, and has had but little pain.

Third Day.—10 A.M.: Temperature, 100°; pulse, 96. 3.30 P.M.: Temperature, 99½°; pulse, 108. 5 P.M.: Temperature, 99½°; pulse, 92. Midnight: To-day she

¹ Billroth and Lücke, *Deutsche Chirurgie* Liefer, 44, p. 136.

² Berliner Klin. Wochenschrift, p. 620, No. 42, 1881.

has taken nearly four pints of koumiss without in the least forcing herself; has received gr. jss. morphia, hypodermically; and fifteen ounces of urine have been drawn. Only once has she had pain. No vomiting.

Fourth Day.—10.45 A.M.: Temperature, $98\frac{1}{4}^{\circ}$; pulse, 84. Commenced giving her the expressed juice of beef-steak cooked rare. 6.45 P.M.: Added pancreatized milk to her menu. 8.30 P.M.: Temperature, 99° ; pulse, 88. Midnight: Dressed the wound to-day, under the spray. The first dressing was found but slightly stained by blood, and was perfectly aseptic. Firm union existed along nearly the whole line of incision. To-day she has received less than gr. j. morphiae. Drew sixteen ounces of urine. Abundance of koumiss, beef juice, and pancreatized milk taken.

Fifth Day.—10 A.M.: Temperature, $98\frac{3}{4}^{\circ}$; pulse, 80. 10 P.M.: Temperature, $99\frac{1}{2}^{\circ}$; pulse, 108. After this the temperature never reached 99° .

Eighth Day.—Sutures removed. Line of union unbroken except at one point in the centre where there was some ectropion of the skin. To this raw surface applied iodoform dressing.

Tenth Day.—Simple enema given, followed by a large and painless stool, the first movement since the operation.

Sixteenth Day.—Out of bed. Morphia has been gradually decreased, and was entirely stopped to-day without any bad results except a slight exhibition of temper on the part of the patient.

Thirtieth Day.—On making an examination to-day, we find the following condition of things: The uterus is freely movable in every direction. Douglas's cul-de-sac is occupied by a knuckle of intestine which can easily be pushed up. On each side, running from the uterine stump of the tubes, and apparently terminating at the posterior vaginal wall opposite the os externum, is a firm fibrous band which is slightly sensitive to pressure. These, I think, are the result of a slight inflammation, which took place on the second day, when her temperature first reached $101\frac{3}{4}^{\circ}$. Beyond this, and the absence of the organs removed, no indication of an operation exists.

Thirty-first Day.—Patient is menstruating. The flow is slight, and she has less pain than at any of her previous menstrual epochs. She has certain nervous symptoms, such as are often seen in women at the menopause.

Remarks.—The diet of this patient for the first few days is mentioned, because I think that it is one of the most important factors influencing cases of laparotomy. For the first twenty-four hours the woman received nothing into her stomach, except, occasionally, a teaspoonful of iced water. Had she been given, as is often done, milk and beef-tea *ad libitum*, her stomach, irritable as it was after the etherization, would most certainly have been markedly disturbed, and the efforts at vomiting would have defeated us in what we strive to obtain in these cases, viz., perfect rest of the abdominal organs. What little vomiting she did was more regurgitation than vomiting, as it was done without effort or nausea. When we did begin to give her nourishment, it was in gradually increasing quantities of the easily assimilated koumiss and peptonized milk. The quantity of morphia administered may seem excessive; but the effect produced upon this *habituée* was not more profound than would follow the taking of gr. j. opii t. i. d. by a person unaccustomed to its use.

107 EAST THIRTY-FIFTH STREET, NEW YORK.

TO DISGUISE THE TASTE OF MEDICINES.—Bitter and nauseous salines are best taken simply diluted with iced water. A mouthful or two of iced water, before or after the dose, to blunt the sense of taste, and the dose between them in a wineglassful of iced water, renders it easily taken by most persons.—*Squibb's Ephemeris.*

Progress of Medical Science.

PROLONGED SUSPENSION OF VITALITY FOLLOWING THE HYPODERMIC INJECTION OF MORPHIA AND ATROPIA.—Dr. Alexander reports the case of a woman, thirty-seven years of age, upon whom an operation had been performed for the removal of the left ovary. At noon, four days after the operation, she became very excited, and disturbed the dressings of the wound, so twelve minims of the hospital solution of morphia and atropine were injected. This represented three-fifths of a grain of morphia and one-fortieth of a grain of atropine. At one o'clock she became livid, and a nurse injected another five minims of the solution before the house-surgeon arrived. When he came he injected ammonia, gave brandy enemata, used artificial respiration, and applied electricity without effect. At 4 P.M., the nurse was laying the woman out, but Dr. Alexander came in and determined to proceed with artificial respiration, galvanism, and frictions. Up to 5.30 P.M., only a spasmodic breath every quarter of an hour, and a feeble beat of the pulse every now and then, could be detected. At 7 P.M., a nurse poured some coffee into the patient's mouth, and she suddenly fell back as if dead, but by turning her over on her side she was made to vomit. By nine o'clock the respirations were beginning to be more frequent and the pulse stronger; she soon became conscious after this, and recovered perfectly.—*Boston Medical and Surgical Journal.*

POISONING BY CARBOLIC ACID.—Mr. E. R. Williams relates the following case in *The Lancet* of August 18, 1883. A young girl, seventeen years of age, was admitted to hospital, having, it was stated, two or three hours previously taken poison, the nature of which, however, it was impossible to learn. She was completely anæsthetic, her muscles relaxed, eyelids closed, pupils dilated and inactive, skin cold and clammy, with large drops of perspiration running down the cheeks, temperature lowered, respiration feeble and shallow, the pulse at the wrist imperceptible, and the action of the heart feeble and intermittent. From this extreme state of collapse, by means of subcutaneous injections of ether, galvanism, etc., she gradually recovered. Careful examination revealing nothing as to the nature of the poison, it was deemed advisable to give her one-eighth of a grain of apomorphia subcutaneously. In fifteen minutes she expelled, with a gush, about five ounces of a dark-colored liquid, smelling strongly of carbolic acid. Having now ascertained what the poison was, the stomach-pump was used, and some olive oil injected. This she soon vomited, together with a little more of the same dark colored fluid. The urine passed was of a dark brown color and gave the usual tests for carbolic acid. The feces were also of a dark color. With the exception of some soreness of the mouth and throat, together with a little pain in the epigastrium, she recovered without a bad symptom, and on the fifth day after admission was discharged. It was subsequently ascertained that she had taken about one ounce and a half of the common crude carbolic acid.

THE TRACTION SUTURE.—Dr. Oscar H. Allis recommends the following device (*Annals of Anatomy and Surgery*, September, 1883) to obviate the tendency of sutures to cut their way out when there is considerable tension of the skin at the edges of a wound: After drying the skin thoroughly, he applies strips of adhesive plaster passing from the margin of the wound in the direction in which the sutures are to hold. The needle is then passed deeply through both plaster and skin, and before the sutures are tightened, an assistant approximates the margins of the wound by pressure from his hands. Sutures employed in this manner, the writer claims, have a firm hold upon the plaster, exert their traction upon a large surface, are less irritating and harmful,

and will continue an efficient action much longer than the ordinary integument sutures.

LYMPHATIC DISCHARGE FROM THE NOSE IN LEUCOCYTHÆMIA.—Dr. Cornil relates the case of a patient suffering from leucocythæmia who had a discharge from the nose of a thick, transparent, glairy fluid. It flowed slowly but constantly, and was neither thin like the discharge of a commencing coryza nor opaque like that of a more advanced nasal catarrh, but contained a large quantity of white corpuscles. The patient did not sneeze nor were there any tickling sensations in the nose. At the autopsy the mucous membrane of the nasal fosse was seen to be smooth, without ulceration, but thickened in places. The thickened parts presented a gray color on section. They were formed by an infiltration of the connective tissue with a mucous, transparent fluid, like lymph. It was this leucæmic infiltration of the Schneiderian mucous membrane which was the cause of the nasal lymphorrhœa.—*Revue Médicale*, August 11, 1883.

TREATMENT OF CORNEAL OPACITIES.—Dr. Michel recommends sulphate of cadmium, of the strength of two and one-half grains to the ounce of mucilage, as an application to opacities of the cornea. A camel's-hair brush, dipped in this wash, is applied to the centre of the spot and retained in contact with it for a few seconds. At first the application is made once a day, but after a while is repeated two or three times in the twenty-four hours. When the pain grows less, the strength of the solution may be increased to five grains or even seven grains to the ounce. When the opacity is of recent formation it rapidly disappears under this treatment, but when it is of old date the applications must be long continued.—*Revue Médicale*, August 11, 1883.

THE MORBID ANATOMY OF IODOFORM POISONING.—Dr. A. Hoepfi found, post-mortem, in four cases of death from iodoform poisoning a condition of fatty degeneration of the heart, liver, and kidneys. The process was only beginning in some, but far advanced in others. The author then instituted a series of experiments upon rats, guinea pigs, and rabbits, administering to them subcutaneous injections of iodoform in oil solution. In every case he found parenchymatous inflammation of the heart, liver, and kidneys. These experiments, however, do not serve to explain the peculiar cerebral symptoms observed in man after poisoning by this substance.—*Allgem. Med. Central-Zeitung*, August 8, 1883.

EXTRA-UTERINE PREGNANCY, WITH RETENTION OF THE FETUS FOR SEVEN YEARS.—A woman, thirty years of age, during the second month of pregnancy, was suddenly seized with violent pains in the lower part of the abdomen, followed by syncope, cold extremities, and vomiting. These symptoms indicated the commencement of a peritonitis, which lasted for three weeks. The pregnancy then proceeded without any further accident. About two weeks before the expected time the pains of labor began, and recurred with regularity and increasing frequency. Even the os began to dilate. Suddenly, after three days, all the pains ceased, the os closed again, and the patient resumed her ordinary avocations. She experienced a little inconvenience at first from an abundant secretion of milk. Six weeks later menstruation was re-established, and for seven years the courses appeared with perfect regularity, and the woman enjoyed excellent health. At the end of this time another attack of peritonitis confined the patient to her bed for several weeks, during which illness she passed a quantity of hair mixed with the feces. Five months later she began to pass little bones with her stools, and in the course of three months very nearly a complete fetal skeleton was thus collected. The bones were perfectly clean of the soft parts. They were in a more advanced stage of ossification than is normal in a child at term. At the time that this case was reported to the Anatomical Society of Paris by Dr. De Brun the woman was in excel-

lent health and still passing one or two perfectly formed bones with each stool.—*Le Progrès Médical*, June 30, 1883.

THE RADICAL OPERATION FOR HERNIA.—From a careful study of upward of four hundred cases, Dr. Leisrink arrives at the following conclusions: 1. The radical operation should never be attempted for the cure of reducible hernia. 2. In the case of very large and painful, or of otherwise incapacitating hernias, the operation is justifiable. 3. Old and feeble persons and very young children should not be exposed to the risks of this operation. 4. The radical operation is indicated after the reduction of strangulated hernia, unless for any reason it be desired to keep the canal open. 5. A radical cure is very seldom obtained; yet (6) the condition of the patient is usually greatly bettered by the operation. 7. In every case a truss should be worn after the operation. 8. The radical operation should always be performed under the most strict antiseptic precautions.—*Deutsche Medicin. Zeitung*, July 26, 1883.

APOPLECTIFORM ATTACKS IN THE COURSE OF LOCOMOTOR ATAXIA.—A man, forty-seven years of age, presenting the symptoms of locomotor ataxia (lightning pains, diplopia, ataxic walk, vesical and rectal disturbances, etc.) suddenly lost the use of his right arm and also the power of speech for the space of ten minutes. Four weeks later similar attacks, involving the entire right side, recurred twenty-two times in twenty-four hours. Each time the power of speech was lost, though the patient was perfectly conscious and could think correctly. Only once was ataxic aphasia (using the wrong words to express well-known objects) observed. A second patient was suffering only from the initial symptoms of tabes dorsalis. This man suddenly lost the power of speech without any paralysis or disturbance of the intellectual functions. In the evening of the same day a second attack occurred, in which consciousness was lost for a period of three-quarters of an hour. Professor Bernhardt states that these attacks were not to be referred to a commencing progressive paralysis with ataxic symptoms, nor were they due to syphilis, heart disease, alcoholism, or any other like condition.—*Deutsche Medicin. Zeitung*, July 26, 1883.

PHOSPHATE OF CODEIA.—Dr. Frommüller employs the phosphate of codeia for hypodermic injection. He says that it possesses the advantage over the muriate and sulphate of being much more soluble (*Memorabilien*, July 16, 1883). The substance crystallizes in slender four-sided columns, is white in color, and of a bitterish taste, and is soluble in four parts of water. Its action is very like that of morphia, but it is milder, and the symptoms of poisoning (such as great weakness, intense headache, bilious vomiting, etc.), are much less often encountered. It seldom causes local irritation when subcutaneously injected. The dose should be at least double that of morphia. The phosphate of codeia is especially recommended in the case of women and children.

THE PREVENTION OF SEA-SICKNESS.—In a communication addressed to the *British Medical Journal* of August 11, 1883, Dr. J. Henry Bennet claims to have discovered a preventive remedy for sea-sickness in the ingestion of strong coffee. He says that some years ago, while travelling from Paris to London, having some time to spare before the sailing of the steamer, he entered a restaurant and drank two cups of *café noir*. To his astonishment he was not ill at all during an unusually rough passage of the Channel, and he was induced to refer his immunity to the action of the coffee. Subsequent experience confirmed this belief. In order to obtain the desired effect, the coffee should be taken long enough before starting to allow of its absorption. Dr. Bennet has always found this simple remedy of great value in short voyages, but he is unable to say whether its influence would continue for a greater length of time than a few hours.

IRREVERENCE AND QUACK ADVERTISEMENTS IN RELIGIOUS JOURNALS.

OUR religious contemporaries, with a few conscientious and commendable exceptions, still persist in their old policy regarding medical advertisements. Indeed, they are adroitly expanding this peculiar line of industry, so as to include the balder and grosser swindling schemes, which promise the guileless reader a phenomenal return on an infinitesimal investment. They should certainly be congratulated on the enterprise which enables them to present in a single copy such multifarious opportunities for the subscriber to refresh his mind, body, and estate. How the editors of these journals have rendered their consciences as elastic as their advertising columns must remain a matter of conjecture.

They can no longer plead ignorance as an excuse, for the expressed opinion of the medical press and the medical profession has been so decided and unanimous, that these gentlemen must know that, as far as the medical nostrums they advertise are concerned, many of them are for disgustingly immoral purposes, and all of them are swindles of the most despicable and pernicious kind. If these gentlemen claim that the papers would not pay without this class of advertisements, they are simply serving "Mammon" for the glory of God. It would be interesting to know to which of the two masters they are more devoted. Most educated people are willing to accord them the benefit of the doubt; but there may very likely be some unsophisticated individuals of a more or less heathen persuasion who would be quite at a loss to decide whether the salvation, whose joyful sound these journals proclaim, is to be considered from a religious or medical point of view. Well may these benighted "innocents" inquire of our editorial Fergusons, "Which is the bust, and which is the pedestal?" What a comfortably adjustable conscience that must be which will not allow a church fair to swell its assets by raffles and dancing, yet permits a journal to increase its income by a more palpable species of immorality. This peculiar kind of piety cannot help but remind us of the familiar anecdote of the grocer deacon and his clerks, which we might appropriately paraphrase to suit the times, and imagine our clerical *confrères* making their rounds through the composing-room somewhat as follows:

"Well, Thomas, have you finished 'Yours for Health?' "Yes, sir."

"And you, Richard, have you set up the Great Indian Secret for the Afflicted?" "Yes, sir."

"Henry, have you completed that Blood Purifier?" "Yes, sir."

"Then let us have prayers."

A short time ago there appeared in one of these medico-religious sheets a report of a prayer-meeting at which the editor was present. In the course of the meeting a young man stated that he had lost his situation because he would not mark goods above their real value. He would not have to sell them, he must merely label them. He preferred to avoid an appearance of evil, and so, though he could ill afford it, resigned. Our brother's remarks thereon were fairly redolent with adulation. Their gist was, "Well done. Take no thought for the future, for the Lord will provide." Ah, friend, you may not label goods falsely, but you advertise them, knowing their labels to be false. The youth at the prayer-meeting would not allow a mote in his eye. Cast the beam out of thine own eye: the Lord will provide. "But you don't indorse your advertisements?" No, we should hope not. But had your young friend said to his worldly employer, "I cannot mark your goods falsely, but if you will label them and give me some printed price lists, I will go on the street and hold a gospel meeting and distribute your lists with my tracts. I will not indorse your cheat, but I will advertise it," would you not have shattered his sophistry, and condemned this act as much as you lauded the other? Alas, sirs, "your actions do belie your words."

Now, brethren, let us follow out your policy a little further. We will suppose, with all reverence, that Christ had delayed his coming until the present century. Would you not deem it a most painful incongruity to see the Epistles of Paul interlarded with patent medicine advertisements? Is not the dignity and responsibility of your trust essentially the same as his? Would you not recoil with horror at the idea of beholding the tablet erected reverently for the loved ones you had lost defiled with the fulsome bait of the sharper and abortionist? Yet, because the tablet takes the form of an obituary notice—a tribute less lasting, perhaps, but surely as tenderly sacred to the bereaved—why is such an insult any less heartless or apparent?

If you are convinced you are justified in allowing these advertisements to appear in your columns, why do you not urge the universal application of your rule of conduct? Any patent medicine firm would print your whole paper if they could monopolize the advertising space. But why stop here? Let all the printing of the Church be done by these firms. If it is right and proper that Sunday-school lessons, hymns, sermons, the Scriptures themselves, should appear in your columns besprinkled with pile remedies and vermifuges, why not everywhere? It is perfectly practicable; try it. Think of the increased usefulness of your Boards of Publication, had they only to furnish the copy and not the cash, to the printer! Some people with antiquated notions might feel a little squeamish about using a Hair Restorer Hymnal or a Kidney Cure Testament in their devotions, but your papers are rapidly eradicating such old-fashioned ideas of propriety. Advise your poorly paid ministers to free themselves and their church from debt by alternating the "usual notices" with extracts from your papers at so much per extract. They would

merely proclaim from the pulpit what you give as Sunday reading at home.

Now, you may declare yourselves shocked and term all this an irreverent tirade, if you please. The irreverence is yours, not ours. Your family physician may tell you of a shock from another quarter. We believe there are few men but what revere, or at least respect, religion, pure and undefiled; but any attempt to spread simultaneously the work of the gospel and the work of the world, the flesh, and the devil, can only excite disgust. Can a journal, any more than a "temple," become in any sense a "house of prayer," while its outer court is but a "den of thieves?" Has the progress of the age permeated the Pilgrim's Progress of to-day, or have you forgotten the simple story of the "Prince of Dreamers." We wonder what honest John Bunyan would think of the manner in which these modern pilgrims pass through Vanity Fair, on their way to the Celestial City. Our old friends, Christian and Faithful, when besought by the merchants to buy their wares, put their fingers in their ears, and raised their eyes aloft, crying, "Turn away mine eyes from beholding vanity!" Our esteemed contemporary pilgrims, whilst zealously saying, "We will have none of your wares," add "We have been told your wares are evil and cannot indorse them, but give us of thy lucre, and we will advertise them." Would there were more John Bunyans alive to day!

A CITY OF MEDICAL SOCIETIES.

DURING the month of October the medical work of societies in this city begins. We give below a calendar showing the extent to which this work has now developed. There are registered in New York City altogether twenty-seven working medical societies, besides two societies devoted to public health, one to general science, one to microscopy, and two to veterinary medicine. There are also four alumni associations, one of which is very active in encouraging medical work.

A large number, indeed the majority, of the societies mentioned below are limited in membership, and hold their meetings at the houses of the members. Their objects are the promotion of friendly intercourse as well as of medical science.

The medical societies of this city have nearly all been the growth of the last twenty years. Of those now organized, not half a dozen existed previous to 1860. Between 1863 and 1870 ten societies, now existing, were organized, and in the succeeding decade nearly as many more.

While some of these local societies are weak and inactive, this cannot be said of the great majority, and the general effect of the existence of the numerous organizations has been most excellent. In no city can there be found so many physicians who are on such amicable terms with each other, nor does any other city produce so many contributions to medical science.

October 1st.—Medico-Chirurgical Society of German Physicians; Morrisania Medical Society. October 2d.—New York Obstetrical Society; New York Neurological Society. October 3d.—Medico-Legal Society. October 4th.—New York Academy of Medicine. October

5th.—Practitioners' Society. October 8th.—New York Ophthalmological Society. October 9th.—East River Medical Association; New York Surgical Society. October 10th.—Pathological Society; Society of Medical Jurisprudence and State Medicine. October 11th.—Harlem Medical Association; New York Laryngological Society. October 12th.—Yorkville Medical Association. October 13th.—Medical and Surgical. October 15th.—Medico-Chirurgical Society of German Physicians. October 16th.—Medical Section Academy of Medicine; New York Obstetrical Society (Private). October 17th.—Northwestern Medical and Surgical Society. October 18th.—New York Academy of Medicine. October 19th.—Roman Medical Society. October 22d.—New York County Medical Society. October 23d.—New York Dermatological; New York Surgical Society. October 24th.—Pathological Society. October 25th.—Obstetrical Section Academy of Medicine; Harlem Medical Association; Clinical Society. October 26th.—Yorkville Medical Association; New York Society of German Physicians. October 27th.—Medical and Surgical Society.

BOVINE VIRUS AND COMMERCIAL ENTERPRISE.

SOME of our Western countrymen have been quick to appreciate the fact that there is money in the bovine virus business if conducted in a certain manner. The *St. Louis Medical and Surgical Journal* states that a firm was organized in September, 1882, for the purpose of supplying "pure bovine virus." In March, 1883, there being considerable small-pox in the city, the Board of Health awarded to this company the contract for supplying the virus. During three weeks over ten thousand vaccinations were made, but without a single perfect success! The contract was at once annulled, but it is evident that if there had been an active epidemic, the consequences would have been most serious. It was afterward learned that the vaccine farm was under the direction of a dry goods merchant!

The lesson is obvious. There is a temptation to make a purely commercial venture of the preparation of bovine virus. The increasing popularity of this form of virus in the United States makes it doubly important that great care should be taken by physicians and health boards to know about the methods of its preparation.

THE LEPROSY COLONY IN TRACADIE.

LEPROSY is a disease but seldom met with in this country, and the cases seen from time to time in some of our large hospitals are too few in number to furnish sufficient data upon which to base any conclusions as to the origin and mode of propagation of the malady. It is said to prevail to a considerable extent in some of the Scandinavian colonies in Wisconsin; but in Tracadie, a small parish on the Gulf coast at the mouth of the Miramichi River, in New Brunswick, it has existed for upward of sixty years. An interesting account of this settlement, and of the lepers' hospital there situated, was published in the *Catholic World* of May, 1877. The writer was not a physician, and his observations possessed more of a social and religious than of a medical interest. Other notices of a similar character have been published since

then in various periodicals, but none of them has added much to our knowledge of the etiology of the disease. A correspondent who visited Tracadie during the past summer sends us a report of what he learned there concerning the origin of the disease in that settlement, from which we take the following condensed account:

The first settlers in Tracadie were the Le Bretons, who went there about the year 1778. They lived with the Indians, upon the coarsest and most meagre fare, and suffered great hardships, yet none of that name has ever had leprosy. The scourge first appeared in 1820 in the person of Ursula Landry, who, with her sister Isabel, came to Tracadie in 1798. They married two brothers by the name of Benoit. Popular tradition says that Ursula contracted the disease by washing the clothes of some French sailors, who were lepers, some time before she came to Tracadie. This explanation of the origin of leprosy in the colony is, however, far from satisfactory, as it is hardly to be supposed that twenty-two years could have elapsed after exposure to contagion before the disease should manifest itself. Ursula died in 1828. The second victim was her sister Isabel, and the third was François Sonier. This man affirmed that he contracted the disease by carrying Ursula's coffin, the sharp edge of which cut his shoulder, and then inoculation was effected by matter running from the corpse. François Sonier was ill a number of years, and his father's house was the rendezvous for the young people of the neighborhood. Several of these were afterward attacked with leprosy. François attempted once to go to Cape Breton to consult some person there who had quite a reputation for curing ulcers, and on the way stopped at the house of one Savoy. A member of the family, Mary Savoy, washed the clothes of the bed in which he had slept, and afterward herself contracted the disease. It was not until a number of persons who were intimate with the Soniers had contracted leprosy that public attention was drawn to it. Then the lazaretto on Shel-drake Island was established (1844).

There are at present twenty-four patients in the hospital, all coming from within a radius of twenty-five miles from Tracadie. From a study of the records, which have been carefully kept since the nuns took charge in 1868, it is seen that the average stay in the hospital was five years. If to this is added two or three years as the duration of the disease prior to the entrance of the patient into the lazaretto, we have an average duration of leprosy of seven or eight years. One patient, however, has been in the hospital for twenty-four years, and another for fourteen. So it would appear that the course of the disease is very variable as regards time.

Our correspondent spent a great part of his time in studying the mode of origin of the leprosy in this place. There are four possible ways, he states, in which the origin and spread of the disease may be accounted for, viz., heredity, endemic influences, contagion, and heredity and contagion combined. Although the general opinion of writers on leprosy is that it is propagated by hereditary influences, yet in no case reported in Tracadie can this be satisfactorily proved. In every instance there was abundant opportunity for contagion, so that the part played by heredity alone could not be determined. The theory of endemic origin is disproved by the fact that the

same conditions of race, habits, mode of living, etc., exist in other places along the coast where leprosy is unknown. The theory of the spread of the disease by contagion is supported by many incontestable facts. Peter Noel came from a perfectly healthy family. He slept during one summer with a man in the advanced stages of leprosy, and in a few years became himself a victim of the disease. A man by the name of McComb, living in a settlement some fifty miles distant, where leprosy was unknown, came to Tracadie and worked for some time in a lumber camp. He returned home a leper, and died. James McGrath caught the disease from Michael Gould. Peter McGrath slept with James, became leprosy and died. Peter lived for a time with the Drysdale family. Seven of Drysdale's children fell victims to the malady. It is a matter of common observation that unless the patients are early removed to the lazaretto, others of the family are attacked; and again, if the sufferers remain at home, but strictly isolated from the rest of the family, the disease is less liable to spread. Finally, it is impossible to account for the rapid propagation of the leprosy in families previously healthy, except on the theory of contagion. On the other hand, facts are not wanting which seem to oppose this presumption. Women have been employed in the hospital for years, washing the clothes of the lepers and scrubbing the floors of the wards, yet they have never themselves become leprosy. Neither the Sisters nor the medical attendant have contracted the disease. The case of one man is related who had lost three wives in succession from leprosy, yet he escaped. Other instances are on record of children, born in the lazaretto of leprosy mothers, and growing up within its walls, who have remained healthy. But these negative facts, however numerous, have much less weight than a few positive ones. Of a number of persons exposed to any contagious disease not every one is attacked. The attendants in the hospital, furthermore, observe every precaution, exposing themselves as little as possible to direct contact with the patients, and living in light and well-ventilated apartments away from the wards.

The following are the conclusions arrived at by the correspondent from his observations of the leprosy as it exists in Tracadie: 1. The origin and early spread of the disease cannot be explained on the theory of hereditary transmission, although this theory may in part account for its further propagation. 2. Although endemic influences, such as climate, mode of life, diet, etc., may be strong predisposing elements, they are in no case the sole cause of the disease. 3. Leprosy in Tracadie was imported from without, and, finding there favorable conditions, was propagated from one person to another by contagion. Finally, leprosy may be regarded as one of the least contagious of diseases, and one which will only spread under a combination of favoring circumstances such as were found in Tracadie.

The lazaretto is clean and kept in perfect order, and everything is done by the Sisters to ameliorate the sad lot of the inmates; but the building is gloomy at the best, and resembles more a prison than a hospital, and it would be a great boon to the suffering patients could a new and more commodious structure be erected. The writer speaks in most grateful terms of the courtesy

shown him while in Tracadie, and desires to acknowledge his indebtedness to Dr. Smith, the Rev. Father Babinneau, the Rev. Mother St. John, and Mr. Young, for much valuable assistance rendered him in his study of the disease. The value and importance of the work done in this humble way in an obscure and wretched village on the shores of the Gulf of St. Lawrence, cannot be over-estimated. To the untiring vigilance of the physician and the nuns in searching out and sequestering every new case of leprosy occurring in the village is doubtless due the fact that it has not ere this spread to other and distant places. For admitting the contagiousness, in however slight degree, of the disease, there are numbers of fishing villages all along our coast in which the condition of the inhabitants would seem to invite its approach, and once it had gained a foothold we would have Tracadies enough at home, and there would be no occasion to go abroad to study the leprosy. There is now good cause for the hope that the disease may eventually be stamped out in New Brunswick, and thus a danger, slight, but none the less real, to ourselves will be removed.

THE HIGH TEMPERATURE OF FEVERS.

THE opinion has been current for some time that the essentials of fever, such as increased pulse-rate, disturbance of the cerebral functions, and, later, certain parenchymatous degenerations, were the direct consequences of increased bodily heat. This widely accepted doctrine is now opposed by Dr. Unverricht. He says that although these so-called febrile symptoms are generally found associated with an elevated temperature, they are not therefore necessarily caused by it. Different kinds of fever are accompanied by varying degrees of cerebral manifestations. Thus a temperature of 103.5° in septic poisoning is associated with great depression of the nervous system. In relapsing fever, on the other hand, a patient bears easily 107° or more. The author cites numerous accurately observed cases to prove that a temperature of over 108° is not of itself fatal. He does not regard Litten's experiments in proof of the evil effects of high temperatures as conclusive, and opposes to them the observations of Volkmann, which go to show that high fever in aseptic conditions may be unattended with danger. Since, therefore, this point is still unsettled, Dr. Unverricht thinks that in the treatment of fevers the question should always be considered whether the harmful effects produced in greater or less degree by all febrifuge remedies will not outweigh the advantage hoped for in reducing the temperature. In fact, he thinks that in certain instances fever may be regarded as a process tending to the advantage of the organism. There is little doubt that since the introduction of exact thermometry into medicine, temperature variations have received a rather undue amount of attention. It is so easy and simple a matter to detect pyrexia and at once prescribe a febrifuge. Pulse observations and other valuable indications have been correspondingly neglected since the thermometer began to assert its claims. But while this much may be readily conceded, we are certainly not prepared to fully endorse Unverricht's opinions. In the ordinary run of febrile affections a high temperature must still be regarded as a

symptom significant of danger. And even if the severity of the individual case need not be gauged by the thermometer alone, the wary practitioner well knows and appreciates the meaning of excessive pyrexia. It is nature's warning that damage, if not already done, may be confidently expected. And from a therapeutical point of view it is quite clear that to be thus forewarned is, in a measure at least, to be forearmed. Expectancy, which is but a misnomer for helpless inaction, is therefore to be deprecated in all such conditions. And we must emphatically oppose the view which sees in fever nature's effort at restitution, and not a morbid process with destructive tendencies.

CARDIAC VERTIGO AND ANGINA PECTORIS.

SYMPTOMATIC, or cardiac vertigo, is an affection which, according to Germain Sée, is not uncommon in cardiac affections, being more frequent in aortic insufficiency, is so common, in fact, that when vertigo occurs in the course of heart disease we need, as a rule, look no farther for its cause. This fact suggests also that in cases of obstinate and distressing vertigo the heart should always be examined, especially if extreme pallor, a prominent symptom of aortic insufficiency, be present and will not yield to medication. In these cases M. Sée affirms that iron is absolutely indicated, though in many cases, on the contrary, iodide of potassium is indicated and gives excellent results. In these cases there are also observed the characteristic pains of angina pectoris coming on every few months, another prominent, though not constant, symptom of aortic incompetence. The anginous pains should of course be combated by hypodermics of morphine, the administration of chloral, or inhalations of nitrite of amyl during the access, and by bromide of potassium and digitalis, or convallaria, during the intervals.

It is interesting in this connection to notice the conclusions of W. Allen Sturge (*Brain*, October, 1882), regarding the etiology of angina pectoris. Having selected a typical case and minutely detailed each symptom as given by the patient, he concludes that the local attack on the heart is due to an organic modification in the substance of the cardiac muscle itself, or some change in the heart acting on the terminal filaments of the cardiac nerves; a commotion spontaneously developed in the gray substance of the sympathetic ganglia of the cardiac plexus, this being transmitted to the spinal cord and brain; a commotion spontaneously developed in the cervical sympathetic ganglia, which give off branches to the cardiac plexus, or in the ganglia of the vagus; a spontaneous commotion in the part of the gray substance of the cerebrum, which may receive impulses coming from above and below; a spontaneous commotion in the parts of the gray substance of the cord in communication with these ganglia by means of bands of nervous substance passing from the cord to the great sympathetic.

Of course a great number of observations are necessary in order to place these scarcely more than theoretical causes on the sound footing of etiological fact. This is recognized by the author, but he is of the opinion—in which most authorities concur—that in the greater number of cases of angina pectoris associated with organic

lesions of the heart or great vessels, the primary irritation probably takes place at the periphery of the cardiac nerves. Dr. Sturge admits, however, that there are cases of angina pectoris which are due to spontaneous lesions of the nerve-centres. Trousseau long ago pointed out the relation between angina pectoris and epilepsy. The paper, though far from conclusive, as the author admits, gives evidence of careful observation, and is an important contribution to our knowledge of this affection.

THE GASTRIC ULCER AND ITS RELATION TO CANCER OF THE STOMACH.

DESPITE considerable study and numerous experiments, our knowledge of the origin of gastric ulcer is still far from satisfactory. Cohnheim, indeed, succeeded in causing an ulceration of the mucous membrane of the stomach by artificially produced embolism and thrombosis of minute gastric vessels. These sores had the form of the typical ulcer of the stomach, but were not chronic and slow of healing as the latter commonly is. Other questions of interest, and, as yet, unsolved, are the mode of cicatrization of the ulcer and the relation, if relation there be, between chronic ulcer and carcinoma of the stomach.

In a brochure, recently published in Leipzig, Dr. Gustav Hauser endeavors, through eighty octavo pages and with the aid of seven plates, to clear up the mystery, and to demonstrate satisfactorily the processes of destruction and repair of gastric ulcer and the subsequent development of cancer. He attributes ulceration of the mucous membrane to an infarction caused by permanent obstruction to the circulation in the fine arterial twigs passing from the submucous to the mucous layers of the stomach. This obstruction may arise from the lodgement of an embolus, from thrombosis or from the rupture of one of these arterioles. The resulting ulcer is chronic only when there is actual disease of the blood-vessels occurring prior to, or at the same time with the infarction. For then the formation of new vessels necessary to the healing process becomes impossible. The more or less chronic course is directly dependent upon the severity of the disease in the vessels. The size of the ulcer is in proportion to the extent of infarction and also to the number of arterioles affected. Any disease of the arteries may give rise to this condition, but atheroma and fatty degeneration seem to play the most important rôle, at least in advanced age. The healing process begins by a sort of puckering together of the base of the ulcer, by which the edges are approximated and close adhesions formed between the mucous membrane and the parts lying beneath it. If the ulcer is extensive, with its base formed of a neighboring organ adherent to the stomach, the cicatrization is not complete, but the mucous edge becomes fixed to the muscular layer or to a greatly thickened connective tissue. This process, the author states, is attended with an enormous hypertrophy and proliferation of the glands immediately about the ulcer. At the same time the normal glandular epithelium becomes transformed into cylindrical epithelium. The hypertrophy of the glands is due to the increased supply of blood during the process of cicatrization, aided by the diminished resistance of the surrounding connective tissue. The glands are excited to increased action, and at the same time

the physiological resistance of the supporting connective tissue is wanting. Regarding the development of cancer in the cicatrix of an old gastric ulcer, the author asserts that such a process may take place. Large ulcers, which never become entirely cicatrized, are especially prone to cancerous degeneration. The disease, he says, begins in the lumina of the glands at the edge of the ulcers which have undergone the changes described above. The abnormal growth of the glandular epithelium continues and finally takes on a malignant character. Between a cancerous growth of the glandular epithelium and an abnormal hypertrophy of the same there is a difference only of degree. In either case, says Dr. Hauser, the causal conditions are the same, viz.: an irritability of the secreting epithelial cells, due to the increased flow of nutrient material, and a diminished resistance of the supporting connective tissue. He relates the history of a case upon which he bases his belief that carcinoma of the stomach may arise from disease of the peptic glands independently of any embryonic germ. As confirmatory of Dr. Hauser's view of chronic ulcer being dependent upon disease of the vessels, may be mentioned two cases related by Dr. Mattei (*Deutsche Medicinal-Zeitung*, July 5, 1883). No sufficient cause could be determined during life for the formation of the ulcers. At the autopsy there was found an amyloid degeneration of the liver and spleen, and a similar change in the gastric vessels had given rise to the ulceration.

News of the Week.

PASTEUR'S INVESTIGATION OF THE CHOLERA IN EGYPT.—The scientific mission to Egypt to investigate the cholera epidemic, for which a grant of 50,000 fr. has just been obtained by M. Pasteur from the French Chambers, consists of MM. Roux, Thuillier, Straus, and Nocard. M. Pasteur has formulated a set of rules for the guidance of his party, by means of which he hopes to guard against infection. All articles of food and drink must be boiled and then kept in heated vessels. Fruit must be washed in boiled water before being eaten. A two-per cent. solution of carbolic acid is to be used for washing purposes.

INCREASE OF THE PARIS HOSPITALS.—The Municipal Council has voted three million francs to be expended in increasing the hospital efficiency of the city. Two millions are to be expended upon the large hospitals already existing. One million constitutes the first instalment for the erection of a hospital for contagious diseases, one for chronic diseases, and one for juvenile incurables.

THE INTERNATIONAL HYGIENIC EXHIBITION at Berlin has closed, but it has been decided to establish a permanent Museum of Hygiene in that city.

ANOTHER NEW MEDICAL COLLEGE.—The Medical Department of Niagara University is the title of a new medical college recently organized in Buffalo, N. Y. It requires attendance upon a three years' graded course, and aims to exemplify the higher education. Judging from the announcement, not much is exacted in the way of preliminary education, although something is required.

PROFESSOR GERHARD LEOPOLD, of Leipzig, has been called to fill the vacancy as Professor and Director of the Royal Institute for Midwives at Dresden.

A NEW BUILDING FOR THE NEW YORK CITY HEALTH BOARD.—A movement is on foot to secure a new and separate building for the City Health Department.

MEDICAL SCHOOL OF HARVARD UNIVERSITY.—ONE HUNDREDTH ANNIVERSARY.—The celebration of the one hundredth anniversary of the establishment of the Medical School of Harvard University, and dedication of its new building, will take place on October 17, 1883. The following is the programme: Part I. (At the Massachusetts Institute of Technology, Huntington Hall, at 11 o'clock A.M.): Address by the President of the University; Oration by Emeritus Professor Oliver Wendell Holmes; Presentation of a portrait of Professor Holmes and a bust of Professor Henry J. Bigelow. Part II. (At the Medical College, Boylston Street): Prayer by Rev. A. P. Peabody, D.D.; Dedication of the new building to the purposes of medical instruction; Reception of subscribers to the building fund, and invited guests, by the Medical Faculty; Exhibition of the building.

DEATH OF DR. F. A. PICKETT, OF REDFORD, N. Y.—Dr. F. A. Pickett died on the morning of the 6th inst., after an illness of three weeks with typhoid fever. He graduated at the University of New York City in 1879, when twenty-four years of age, after which he removed to Redford, N. Y., where he practised until his death. He left a large and lucrative business by his sad and untimely death.

PRIZES FOR NEW REMEDIES IN TYPHOID FEVER.—Acting Assistant J. M. Main, of the Marine Hospital Service, reports from Brownsville, Texas: "The Medical School of the city of Mexico has called a convention of physicians to determine the properties and uses of simabacroni—its pharmacology, chemical analysis, and physiological action—demonstrated by experiment, with a view of ascertaining its usefulness in the treatment of typhoid fever. A prize of \$500 is offered for the best thesis on the subject; also a premium of \$500 for the best thesis on the usefulness of pulque in typhoid fever. Pulque is a refreshing beer from the heart of the maguey (*Agave Mexicana*). The President of the republic has appointed a sanitary commission which is to meet first at Vera Cruz during the present month. Its object is to consider and discuss questions of hygiene, disinfection, and prophylaxis."

YELLOW FEVER.—At Vera Cruz there were nineteen deaths from yellow fever during the ten days from August 20th to 30th.

No case of yellow fever has appeared in the city of Pensacola, the disease having been confined to the Naval Reservation.

Acting Assistant Surgeon J. M. Main reports, under date of September 3d: "Yellow fever has broken out at Tlacotalpan, and is spreading in a northerly direction. It has not reached Tuxpam. Tuxpam has enforced quarantine against all infected ports and inland cities. Typhus fever has appeared recently at Zacatecas. The death-rate is said to be ninety per cent. Small-pox is very fatal at Progreso; mortality 52.5 per cent. Yellow

fever has appeared at Campeachy, carried there by a Norwegian vessel. At Real del Monte typhus fever is prevailing, mortality being ninety per cent."

Sanitary Inspector Daniel M. Burgess, of the Marine Hospital Service, reports from Havana: "There were 708 deaths in this city during the month of August. Of the decedents 152 were by yellow fever, 19 by typhoid fever, 3 by bilious fever, 23 by intermittent, remittent, and pernicious fevers, and 1 by diphtheria. During the week ending September 7th there were 18 deaths by yellow fever, nearly all of them being among private citizens. The reduction in the mortality by yellow fever is not from any tendency in the disease to cease to spread, but from the want of material for it to feed upon, and the mild type of the epidemic or endemic. Some wharves are very dangerously infected, and all vessels which go to them and stay over three days are almost sure to suffer and become dangerously contaminated. Within the last two weeks whole crews of vessels laying at those wharves (liable to have yellow fever) have either had it while the vessel was there or soon after leaving. The navy and army have suffered very much, and the few remaining ones who have not had it continue to fall sick."

DEATH OF LOUISE LATEAU.—The death is announced of Louise Lateau, the Belgian stigmatisée, of Bois d'Haine. She was thirty-three years and seven months of age at the time of her death. Her case excited considerable interest at one time, and she was subjected to numerous medical investigations. Virchow, it is said, was asked to see her, but was unable to do so. On every Friday, it was said, she fell into a state of ecstasy, and blood flowed from the stigmata in her hands and feet.

DR. LOUIS F. PELTON, of Mount Kisco, died on Monday, leaving a widow and two sons. He was graduated from the New York University Medical College, in 1847.

AN UNPLEASANT EXPERIENCE.—Dr. William E. Beardsley, of Brooklyn, was recently called to attend a woman who was suffering from dyspnoea. He administered some aromatic spirits of ammonia, and, no relief ensuing, was about to repeat the dose, when the patient fell back dead in his arms. The husband, crazed with grief, rushed upon the doctor exclaiming, "Did I call you here to murder my wife?" and proceeded to do his best to murder the doctor. The man was a stout German, and Dr. Beardsley was considerably bruised in the encounter, and might have received very serious injuries had it not been for the timely intervention of others in the house.

THE LATE DR. J. D. TRASK, OF ASTORIA, N. Y.—It is seldom that the death of a physician is looked upon as a public affliction by the community in which he has labored. So it was, however, in the case of the late lamented Dr. Trask. The rich and poor crowded the church to pay their last tribute of respect to one who had served them so faithfully during life. The stream of mourners continued to file past the casket until long after dark, and even after the congregation had left the church many came to bid farewell to the dead who had been unable to attend the funeral services earlier in the day.

The scene throughout was one provocative of many sad reflections. There was an intensity about the grief of those present that is very rarely witnessed. The several departments of the City Government, the Citizens' Committee of Fifty, the Law and Order Society, and various other bodies were represented, besides which several distinguished members of the medical profession from New York City and other parts of the State were present. The big bell of the Church of the Redeemer and the fire bell were tolled at minute intervals during the afternoon and up to the time of the commencement of the service. As an author, practitioner, citizen, and Christian he did his work effectively, quietly, conscientiously, and for the work's sake. It would be well if such could be said of all of us.

AMERICAN ACADEMY OF MEDICINE.—The annual meeting of the Academy will be held at the New York Academy of Medicine, 12 West Thirty-first Street, New York, on Tuesday, October 9 (three o'clock P.M.), and Wednesday, October 10, 1883.—RICHARD J. DUNGLISON, Secretary.

A GOLD MEDAL TO W. H. SCHIEFFELIN & CO., OF NEW YORK.—Among the awards announced to exhibitors at the Holland International Exhibition at Amsterdam was a *gold medal* to Messrs. W. H. Schieffelin & Co. for their soluble pills and granules. This is a special distinction for their reliable preparations, as the award was made after a careful analysis of specimens of Messrs. Schieffelin's manufactures by the Government chemists.

THE ASSOCIATION OF GERMAN PHYSICIANS AND NATURALISTS held its fifty-sixth annual session at Freiburg, beginning September 17th.

COPPER AND CHOLERA.—M. Bailly, of Chambly, has adduced evidence that copper is not a prophylactic against cholera as asserted by M. Burq. An experience of sixteen years in connection with a factory where workmen are largely employed in copper has shown that the *employees* are not exempt from cholera, typhoid fever, or other infectious disease.

SLIGHTLY PREMATURE.—The Chicago police have certainly not been carefully instructed in the signs and tokens of death, as the following incident will show: A man named Lewis Lacy entered a street-car in that city a few days since in a drunken condition and refused to pay his fare. The conductor threw him off the platform, and seeing he did not move, told the driver to whip up, and the car rattled away and the conductor escaped. The police patrol was called, the body was put in a wagon, taken to the morgue, and placed on ice, while a large force of police were sent in search of the fleeing conductor. After being a short time on ice the body began to show signs of life, and in the course of half an hour Lacy was able to walk to the police-station. An examination showed he was not seriously hurt, and that his state of temporary coma was due wholly to liquor.

DEATH OF DR. SYLVESTER F. MIXER.—Dr. S. F. Mixer, of Buffalo died on September 17th. Dr. Mixer was born in Morrisville, Madison County, N. Y., De-

cember 27, 1815. He graduated from the Medical Department of Yale College when twenty-six years of age, and immediately began the practice of his profession in Buffalo. Six years later he took the degree of M.D. from the College of Physicians and Surgeons in this city. He was a prominent member of the Buffalo and Erie County Medical Societies, and the American Medical Association. From 1858 to 1874 Dr. Mixer was Attending Physician to the Buffalo City Hospital. He then became Consulting Physician to the same institution.

PROFESSOR MÜNCH, of Kiew, has been ordered to Egypt to study the cholera.

PROFESSOR BIZZOZERO has received the Riberi Prize of 20,000 francs for his investigations into the physiology and pathology of the blood.

YELLOW FEVER has appeared at Guaymas, Mexico.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE—MEDICAL SECTION.—We reported some of the work of this meeting in the last issue of THE RECORD. At the meeting, August 20th, M. Burot made a communication upon the "Variations of the Chlorides in the Urine." He showed an apparatus for the easy and rapid quantitative measurement of these chlorides. It consisted of a graduated tube and pipette, a solution of nitrate of silver (28.40 grammes per litre), and a solution of chromate of potassium. M. Onimus sent a communication upon a case of "Infantile Pseudo-paralytic Contracture." The patient had in all the extremities muscular tension, exaggerated reflexes, and contractures. All the members could be moved, but the effort was attended with ataxic chorea-like movements. No atrophy was present. Onimus referred the lesion to the upper part of the pons. M. Apostoli read a paper upon the "Electrical Treatment of the Ovarian Pain in Hysterics." M. Boucheron opened a discussion upon "The Pathogeny of Retinal Detachment." He referred especially to the rheumatic theory of its origin. M. Bouchut called attention to the "Relation between Intercostal Neuralgias and Angina Pectoris." He related the history of three patients suffering from intercostal neuralgia who were suddenly seized with angina pectoris. Other instances illustrating this transfer of morbid action were given. M. Verneuil presented a learned but not particularly instructive paper upon "Traumatic Auto-involution." M. Nepveu read a paper in which he claimed that micrococci were always present in the fluid of the peritoneal sac in strangulated hernias. Antisepsis should be applied accordingly. M. Leudet read a paper upon "Ulnar Neuritis caused by Repeated Contusions in following Certain Occupations." Carpenters, in planing, dyers, calico-printers, and shoemakers were especially liable to this trouble. M. Maurel read a paper upon "Normal and Pathological Albuminuria." He presented a somewhat original division of the albuminous fluids of the body. They are, he said, of two kinds: Those which are colored violet, and those which are not so colored by a solution of copper sulphate in potassa. In the latter class are the albumens passed in the urine during the acute fevers. In pathological albuminuria, or Bright's disease, the albumen passed is colored violet by the solution referred to.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

Eighth Annual Meeting, held in Philadelphia, Pa. September 18, 19, and 20, 1883.

TUESDAY SEPTEMBER 18TH—FIRST DAY—MORNING SESSION.

THE Society met at the College of Physicians and was called to order at 10 o'clock by the President, DR. GILMAN KIMBALL, of Lowell, Mass.

MEMBERS PRESENT.

The following answered to the calling of the roll by Dr. Frank P. Foster, of New York, Secretary: Drs. Kimball, of Lowell; A. H. Smith and Parvin, of Philadelphia; Barker, Polk, and Emmet, of New York; Mann, of Buffalo; Johnson, of Washington; Wilson and Howard of Baltimore; Reeve, of Dayton, O.; Ingham, of Philadelphia; Jackson, of Chicago; Reamy, of Cincinnati; Van de Warker, of Syracuse, N. Y.; Campbell, of Augusta, Ga.; Byrne, of Brooklyn; Duer, of Philadelphia; Byford, of Chicago; Palmer, of Cincinnati; Sutton, of Pittsburg; Battey, of Georgia; Chadwick and Lyman, of Boston; Goodell, of Philadelphia; Gillette, of New York; Browne, of Baltimore; Reynolds, and Baker, of Boston; E. Wilson, of Philadelphia.

The address of welcome was delivered by DR. EDWARD DUER, of Philadelphia.

INVITED GUESTS.

The Council recommended the following: Alfred Stillé, M.D., President Philadelphia College of Physicians; William M. Welch M.D., President Philadelphia County Medical Society; Richard A. Cleeman, M.D., President Philadelphia Obstetrical Society; James Tyson, M.D., President Philadelphia Pathological Society; Robert P. Harris, M.D., of Philadelphia; I. R. Page, M.D., and Robert T. Wilson, M.D., of Baltimore.

The first paper was read by DR. JOSEPH TABER JOHNSON, of Washington, D. C., on

SUPERINVOLUTION OF THE UTERUS.

Sir James Simpson described this disease over thirty years ago, and stated that his patients remained fully uncured. Dr. Johnson introduced the subject, with the hope that discussion might follow which would throw light upon a hitherto obscure class of cases. Barnes believes that this condition is uncommon. One writer has found it to occur in about one per cent. of all cases. Dr. Cole, of San Francisco, has seen many of these cases. It must be differentiated from atresia of the uterus. Simpson claims that it may occur in the same connection as undeveloped uterus and other processes not involving an inflammatory process. The extent may vary from the slightest shortening to entire obliteration of the uterus and ovaries, as has been reported by Whitehead. The term implies that superinvolution only occurs after the process of involution has been set in progress by the emptying of a uterus once occupied by some mass or body which has produced its increase in size beyond the normal point, as, for instance, after cases of hydrometria, pyrometria, hydatids, or removal of the ovaries, uterine tumors, as well as upon the conclusion of utero-gestation or abortion.

Dr. Johnson then related the history of four cases occurring in his own practice, and concluded with a brief summary of the literature of the subject, so far as he was familiar with it. The points on which all writers on this subject agree are that excessive involution does occur from some cause; that electricity should be tried; and that in the great majority of cases it is incurable.

DR. BARKER, of New York, suggested, with regard to the term superinvolution, that it might with propriety be used in all cases where retrograde process has taken place to an extreme extent from any cause, as fibroids, acute uterine catarrh, etc. With regard to frequency, he thought it a difficult point to decide, but, for himself, was inclined to the opinion that it occurred quite as frequently as indicated by the author of the paper. In the large majority of cases no benefit can be given by treatment. One practical point was not referred to by any writer, so far as he had seen, and that was with reference to the class of cases which could be benefitted by treatment. Whenever he found superinvolution of the uterus associated with evidence of arrest or defective ovulation, very little could be effected by treatment. On the other hand, cases associated by evidence of any active ovulation, he thought could be cured sometimes, and the proof had been in the fact that the symptoms had disappeared, pregnancy ensued, etc. The symptoms which gave evidence of the existence of ovulation, associated with this condition of the uterus, were disturbances of the vascular and nervous systems at or near the menstrual period, such as intense headaches, flushing of the face and congestion of the eyes, pelvic pain, and sense of dragging, with nausea and vomiting, etc. The point he made was that superinvolution associated with functional activity of the ovaries might be benefitted by treatment. Galvanism was one of the prominent agents which he had employed.

DR. REEVES JACKSON, of Chicago, thought the question of differential diagnosis between superinvolution and the occurrence of premature climacteric was a difficult one to decide in some cases, and cited the history of a case. Whether or not the condition is one originating in the uterus was regarded by him as a question of great practical importance. If there is functional activity in the ovaries it may be assumed that the small size of the uterus does not depend upon disturbances of its own vascular and nervous supply, primarily.

DR. VAN DE WARKER, of Syracuse, thought the cases might be divided into those which show the cervix only involved and those in which the condition affected the body of the uterus as well. There are cases in which involution is confined to the cervix, the proof of which, can be found in certain cases of laceration of the cervix when the posterior lip is very much atrophied and the anterior lip in very nearly its normal condition. He thought Dr. Johnson's first case was one of that character.

DR. H. P. C. WILSON, of Baltimore, thought it exceedingly rare to meet with the condition described in the paper by Dr. Johnson. He was able to recall only two or three cases of superinvolution in women who have borne children, or had miscarriages or premature labors. He thought that in the cases in which the ovaries existed in the normal, or nearly normal condition, and were normally active, benefit might follow treatment.

DR. BATTEY, of Rome, Ga., said that in the majority of cases in which he had performed the operation with which his name had been associated, superinvolution of the uterus had followed, and in quite a number of cases it had been extreme. In many of the cases the uterus was apparently healthy at the time of the operation. He thought the question of superinvolution was one affecting the ovaries rather than the uterus; it is want of proper ovulation.

The discussion was continued by Dr. Byford, of Chicago, Dr. Campbell, of Georgia, and closed by Dr. Johnson.

THE IMPORTANCE OF CLEANLINESS IN SURGICAL OPERATIONS.

DR. R. STANSBURY SUTTON, of Pittsburg, Pa., read a paper on the above subject, in which he gave a review of ideas and theories entertained from time to time since Galen taught down to the present, concerning the real na-

ture and treatment of this important class of cases. The germ-theory received a large share of attention, coupled, and justly so, with the name and method of Mr. Lister. The conclusion reached by the author was that the best success in the treatment of surgical wounds came chiefly from cleanliness rather than from the use of antiseptics, technically speaking. Special personal attention must be paid by the surgeon to all the details, regulation and preparation of assistants and nurses, preparation of instruments and ligatures, exclusion of sponges, etc.

DR. S. D. GROSS, of Philadelphia, was invited to open the discussion. He thanked the Society for the compliment extended, but declined, for the reason that he came to listen and to be instructed.

DR. LUSK, of New York, thought that for the greatest number of operations the spray could be used with positive advantage, and cited four cases, all complicated, in which he operated in Bellevue Hospital with satisfactory results under unfavorable circumstances.

DR. WILSON favored the use of spray to render the air of the operating-room antiseptic, but did not continue it during the performance of the operation.

DR. CAMPBELL, of Augusta, Ga., referred to surgery as practised in the days before the antiseptic method was brought forward, and he was of the opinion that, all in all, about as good results were obtained then as now. Cleanliness was observed then and care in the performance of the operations.

The discussion was closed by Dr. Sutton, after which the Society adjourned to meet at 3 P.M.

FIRST DAY—AFTERNOON SESSION.

The Society was called to order by the President.

Drs. R. B. Maury, of Memphis, Tenn.; Wm. E. Moseley and Wm. P. Chunn, of Baltimore; and Samuel D. Gross, of Philadelphia, were elected

INVITED GUESTS.

DR. ALBERT H. SMITH, of Philadelphia, then read a paper on

HOT WATER IN SECONDARY HEMORRHAGE AFTER PELVIC OPERATIONS,

in which he stated that while the general value of this agent had been recognized since attention was first especially directed to it by Dr. Emmet, of New York, who gave Dr. Pilcher, of Detroit, credit for the original suggestion, and while it received constant employment in the larger cities, he had been impressed with the idea that in other localities its specific action had not been fully appreciated. Dr. Smith had used it with great advantage in hemorrhage occurring with pregnancy, and also in post-partum hemorrhage. It may be used as a prophylactic against hemorrhage in every case of labor, and also against local absorption. He regularly employed it in hospital practice for this purpose, injecting the vagina with water at a temperature of 115° to 120° F., sufficiently impregnated with some disinfectant, in every case of labor, simple or complicated, and continued the injection until the water returned without tinge. To its use after plastic operations especially he wished to direct attention. In secondary hemorrhage from opening of large vessels we have in the hot-water douche a means for its control of which he wished to make special mention. Dr. Smith then referred to cases reported in a lecture recently published from Dr. Skene, of Brooklyn, and expressed himself surprised, in the first place, that Dr. Skene had found that the hemorrhagic diathesis prevented the performance of operations, and more surprised that he had been unable to control hemorrhage during operation. Dr. Skene had ignored entirely the virtues of the hot-water douche. Dr. Smith was perfectly satisfied that it would arrest hemorrhage in cases precisely like those reported by Dr. Skene, as well as in many other cases in which

bleeding of an alarming character occurred. He then related the history of cases in which he had used this agent with most satisfactory results. He wished to direct attention to three points: 1, the great advantage of the hot-water douche over all means for arresting secondary hemorrhage; 2, its entire efficiency as a hæmostatic where it can be carried to the source of the hemorrhage; 3, the simplicity of its application.

DR. REAMY, of Cincinnati, briefly referred to the merits of this remedy, and said that for some time it had been his custom to have a stream of hot water running over the surface during the perineal operation, instead of using sponges.

Drs. Chadwick, of Boston, Goodell, of Philadelphia, and H. P. C. Wilson, of Baltimore, spoke of the efficacy of the hot-water douche as a hæmostatic.

DR. CAMPBELL, of Augusta, Ga., indorsed what had been said in favor of the hot-water douche. So far as post-partum hemorrhage was concerned, he had relied upon iodine, as recommended by the late Dr. Trask, for its control—one part of tincture of iodine to three or four of water, and injecting it into the uterine cavity. Dr. Campbell also said there were two kinds of hæmostatics; one which acts on the calibre of the bleeding vessels, causing them to contract and so arrest the bleeding, the other acting chemically on the blood, and so plugging up the lumen of the bleeding vessel. The first kind is of service in post-partum hemorrhage, the second answers only for the arrest of hemorrhage in cases where it is necessary to produce a clot to obstruct the circulation.

DR. GOODELL referred to the efficacy of hot vinegar as a hæmostatic.

DR. MANN, of Buffalo, referred to a case in which he was unable to control the hemorrhage with the hot-water douche.

DR. GOODELL thought Dr. Mann's case was one in which it should not be expected that the hot water would arrest the hemorrhage. [Cutting of the circular artery in cancerous tissue].

DR. BARKER asked what hæmostatic shall be used when the delay of fifteen or twenty minutes for the hot water to act could not be permitted without imminent risk of losing the patient's life. He was not prepared to answer the question. He had used in one such case the gentle application of cotton, wet in Squibb's fluid extract of ergot, and simply threw it out as a suggestion, that it might also possibly be of service in other cases.

The discussion was closed by Dr. Smith.

DR. C. D. PALMER, of Cincinnati, then read a paper entitled

SOME POINTS CONNECTED WITH THE SUBJECT OF DYSMENORRHOEA.

That this condition is mechanical in its origin is one of the most natural conclusions. In a certain proportion of cases obstruction in the uterine canal exists, and in the region of the external os most frequently. But the interest in the paper centred in the arguments to prove that the disease is not mechanical in character, but a functional disease, essentially a neurosis. Dysmenorrhœa occurs without any abnormal condition of the uterus which can be detected. There are instances in which well-defined abnormalities of the uterus exist, and yet there is no dysmenorrhœa. There are cases of stenosis without menstrual pain. There are cases of well-defined flexion and yet no dysmenorrhœa. Other points similar in character were made by the author of the paper. In all cases treatment should be purely constitutional until the necessity for local exploration becomes apparent and justifiable. The dysmenorrhœa expresses a fault in the nervous system at large, and local treatment may be united to thorough attention in that direction, but the cases requiring it are very rare after thorough general treatment has been tested. Iron when the flow is scanty and lacks color; arsenic when the flow is prolonged and too frequent. The virtues of iron may be increased

by the addition of *nux vomica*, phosphorus, etc. Electricity may be of service, especially in the partly neurotic, spasmodic, rheumatic forms of the disease. He had used a combination of bichloride of mercury and iodide of potassium with good results, independent of any specific disease. Two remedies he directed special attention to: 1, concentrated tincture of *cimicifuga racemosa* in moderate doses three days prior to the period and continued in smaller doses throughout the flow; 2, tincture of *pulsatilla* given in a similar way. Dilatation is indicated only in the neurotic spasmodic forms, and then after failure of medical and constitutional treatment. If stenosis of the canal exists, it may be opened up by incision; and if it does exist it should be opened up before secondary complications caused by it are developed.

DR. CHADWICK, of Boston, said that he had listened to the paper with great satisfaction, because it contained much the same teachings which he had been accustomed to give for several years. He had been gradually giving up the belief in structural constriction of the cervical canal, and consequently the belief in obstructive dysmenorrhœa.

DR. BARKER, of New York, regarded the subject as one of great interest and importance, and had listened to the paper with much pleasure. In most respects he was in thorough accord with Dr. Palmer, and rose merely to supplement the paper with some new points concerning treatment. He believed that mechanical obstruction, as a cause of dysmenorrhœa, existed in only a small percentage of cases. That it does exist in some cases, he thought all were convinced. On the other hand, patients who have had dysmenorrhœa until they became mothers have had the dysmenorrhœa return just as badly as before when menstruation has been re-established; and, therefore, as had been stated by Dr. Chadwick, while dysmenorrhœa and mechanical obstruction may co-exist, they do not necessarily bear the relation of cause and effect. He believed there are two forms of dysmenorrhœa—one dependent upon the uterus itself, and the other ovarian. Either form may be painful, but he believed that by careful inquiry a differential diagnosis could be made between them. In the uterine form there are cases which do not depend on obstruction, and which are yet attended by great pain up to the time of the flow; but as soon as the flow begins the pain ceases, and the patient is comparatively easy during the remainder of the period. In such case he regarded the pain as due to an effort of the uterus to get rid of the plethora by rupture of capillaries, etc. These two forms occur both in plethoric women and in those whose general condition is the ideal standard of health.

With regard to treatment for these varieties he fully agreed with the author of the paper concerning the efficacy of iron; but the preparation which he had usually prescribed had been the lactate, three to five grains three times a day, generally associated with chlorate of potash. This treatment is begun about ten days before the menstrual period should appear. Another remedy, which is almost specific in uterine dysmenorrhœa, is *apiol*; but to get its good effects its use should be begun at least *two days before* the period should return, and kept up in the period. Give *two* capsules, usually, after each meal.

There is another class of cases in which the flow is unattended by pain until it has continued for two or three days. These patients are usually strong, of full habit, complain of headache, vertigo, imperfect vision, etc., previous to the period. These belong to the ovarian variety, and here he uses the bromides, preferably the bromide of sodium, beginning about a week before the period and administering from ten to fifteen grains in the middle of the forenoon, afternoon, and at bedtime. *Apiol* is also serviceable in these cases.

The further discussion of Dr. Palmer's paper was postponed until the reading of papers had been completed.

The Society then adjourned to meet at 10 A.M. on Wednesday.

WEDNESDAY, SEPTEMBER 19TH--SECOND DAY--MORNING SESSION.

The Society was called to order at 10 A.M. by the President.

DR. GILMAN KIMBALL, of Lowell, Mass., President, then delivered the annual address, which consisted of a

BIOGRAPHICAL SKETCH OF DR. NATHAN SMITH, FOUNDER OF THE DARTMOUTH MEDICAL COLLEGE,

the genius, indomitable will, untiring energy of whom, the speaker believed, had done more for practical medicine and surgery than that of any other single individual in this country. With regard to his connection with the subject of ovariectomy, he was the second to perform it successfully in this country, the operation taking place at Norwich, Vt., in July, 1821. It was as truly original as was the first performed by McDowell, and simply by priority of date was McDowell distinguished beyond dispute as the father of ovariectomy. It was not Dr. Kimball's purpose to raise any question as to the justice of this claim, now acknowledged throughout the civilized world. While listening to the memorial address by Professor S. D. Gross, at the unveiling of the monument erected to McDowell, it occurred to him that something more might justly be said than to merely chronicle the fact by saying that Smith had the courage to follow in the footsteps of McDowell.

The President then gave a biographical sketch of Dr. Smith, who was born of respectable parents in Massachusetts, September, 1762. From this point the speaker traced the career of the subject of his discourse through his school days, entrance upon his professional work, and his subsequent labors as a physician and surgeon, in which were exemplified "the eagle's eye, the lion's heart, and a woman's hand."

The address closed with special reference to the operation of ovariectomy, and the opinion was expressed that, in point of absolute merit, Dr. Nathan Smith is entitled to the same honors which have been bestowed upon Ephraim McDowell.

After a few complimentary, and to a certain extent critical remarks by Professor S. D. Gross, of Philadelphia, DR. REAMY, of Cincinnati, read a paper entitled

A RARE FORM OF ABDOMINAL TUMOR.

The author of the paper related the history of three cases. The leading features as presented in the first case, seen in consultation, in July, 1878, were the following; as they existed in a patient thirty-eight years of age, married fifteen years, sterile, and in ordinary good health up to three years ago, and who was supposed to be suffering from ovarian tumor. The growth was abdominal, in front of the intestines, cystic, and contained fluid. It had no connection with either the uterus or its appendages, and no special change was produced in the condition of the abdomen whether the patient was in the upright or horizontal position. The fluid, removed by tapping, was red and contained blood-corpuscles, both in good condition and broken down. The paper closed with a brief reference to the scanty literature of the subject—namely, tumors of the omentum, and the three cases reported belonged to the variety of bloody. Microscopical examination revealed the tumor (the specimen presented) to be sarcoma.

DR. C. C. LEE, of New York, thought the cases belonging to the group described by Dr. Reamy were very rare, and that the possibility of diagnosing sarcoma of the omentum before induration had occurred had not been established. He could conceive that if the general rule of tapping was established this class of cases would become much better known than at present.

DR. SURTON, of Pittsburg, thought it impossible, beforehand, to determine whether, in any given case of tumor of the omentum, the disease was sarcomatous or carcinomatous. But if the tumor contains fluid, he

thought it dangerous practice to use either the aspirator or trocar. If the surgeon feels justified in opening the belly to obtain fluid for examination, use the hypodermic syringe. Besides, Dr. Sutton believed, in the present stage of surgery, that the operator is justified in discarding all punctures and in opening the abdomen by an exploratory section. If it is believed that the tumor is malignant after the opening has been made, the best surgery is to close the wound without interfering with the growth.

DR. CAMPBELL, of Augusta, Ga., thought that such growths were apt to be pedunculated, and that it was well, therefore, to remove the tumor and give the patient an additional chance.

DR. REAMY believed that, all things considered, tapping is a justifiable procedure, at least for the relief of symptoms. In two of his cases the operation was followed by recovery, and he believed it to be as well to tap as to cut the belly open.

A paper by DR. JENKS, of Chicago, on

A NEW METHOD OF OPERATING FOR FISTULA IN ANO,

was read by title.

DR. H. F. CAMPBELL, of Augusta, Ga., then read a paper on

CONGENITAL FISSURE OF THE FEMALE URETHRA, WITH EXTROPHY OF THE BLADDER.

A case was reported, and the interest centred in the question, When is the proper time to operate? It is a matter of quantity of tissue and space. He held that after puberty the operation might be performed with prospect of better result than if performed with the present limited quantity of tissue and space. The patient was a young female child.

DR. BROWNE, of Baltimore, related the history of a case with calculi, occurring in a child eight years of age. He proposed to perform the supra-pubic operation, and remove the calculus, but the family postponed it and the child died.

DR. MANN, of Buffalo, narrated a similar case to that reported by Dr. Campbell, and in which he advised operation at once, which was performed by Dr. Minter, of Buffalo, and with completely satisfactory results.

DR. T. ADDIS EMMET, of New York, then read a paper entitled

A STUDY OF THE ETIOLOGY OF PERINEAL LACERATION, WITH A NEW METHOD FOR ITS PROPER REPAIR.

During the last twenty years the author of the paper had given more thought to this subject than to any other likely to be brought before the Society. He had reached the conclusion that simple laceration of the perineum, extending even through to the sphincter, but not involving it, produces no inconvenience after the parts have once healed, except by the disturbances occasionally found of a reflex character from the presence of cicatricial tissue. It has been frequently observed that the disturbance after laceration of the perineum is not in proportion to the extent of the injury; also that the perineum has been lacerated for years without causing inconvenience; on the other hand, it has been equally puzzling to explain the amount of suffering attending the slightest degree of injury; and again, that the same kind and amount of suffering is experienced when no injury of the perineum has been received.

Notwithstanding the many modifications of Baker Browne's operation, Dr. Emmet believed that no one had relieved any of this class of patients by simply uniting the tissues which had been lacerated, and no more. *Some portion of the posterior vaginal wall must be engaged in the line of union in order to secure any benefit.* The true condition of the parts he regarded as a rupture of the pelvic fascia reflected over the muscles of the vaginal outlet,

and that to afford relief this fascia must be restored as nearly as possible to its original position.

In the operation it is useless to carry denudation so far externally as is often done. It should be limited to the true osteum vaginae, and the perineum should be further strengthened by bringing forward a transverse fold of the posterior wall of the vagina, even if there is no rectocele. The mistake should be avoided of taking too much of the posterior wall. The essential features of the operation are as follows: Make two transverse crescentic denudations, an outer one with concavity looking backward and an inner one with the concavity looking forward. To establish the situation of these crescents, three tenacula are to be employed. With two of these instruments the open mouth of the vagina is to be brought together by inserting the points at the level of the upper limit of the remains of the hymen, one on each side. The points thus seized would mark the extremities of the anterior crescent, and while they are held together with the instruments the third tenaculum is to be inserted in the posterior vaginal wall in the median line, at a point that could be drawn forward to meet the two former without giving rise to undue tension. This point would mark the centre of the posterior crescent. The denudation having been effected, the two crescentic denuded patches are to be stitched together. This has the effect of drawing the tissue of the perineum upward so that the vertical rent in the median line will be much shortened, and can now be closed with a few sutures, the last step not being essential.

The paper gave rise to a considerable number of questions, which Dr. Emmet answered, and illustrated his plan of operative procedure upon the black-board. The discussion of the paper was postponed until the afternoon session.

The Society then adjourned to meet at 3 P.M.

SECOND DAY—AFTERNOON SESSION.

The Society was called to order by the President.

Dr. Emmet's paper being before the Society for discussion, the author gave a brief *résumé* of his views as follows: Laceration of the perineum does not produce the trouble which is attributed to it. It is never lacerated as it seems to be; there is no such tissue there. The tissue in front of the rectum is frequently thicker than before the injury. No such body exists as the perineal body as it is represented in the books, and as operators strive to restore. The injury is more apparent than real. He held that even if the laceration of the perineum is not repaired the injury can be best repaired by bringing together a certain portion of the posterior wall of the vagina just at the entrance of the vagina, where it joins with the soft parts. He further held that we may exclude, in performing any operation, everything with reference to the external organs of generation outside of the line of the hymen around the vagina. The fascia, forming two sulci, is as important to keep up the perineum, the posterior wall of the vagina against the anterior wall, as a pair of suspenders is to keep the seat of a pair of pantaloons in place. By his operation, bringing a fold of the posterior wall of the vagina up, we restore the attachments and support, and may let the perineal injury go entirely, if the operator chooses to do so; it matters little whether or not stitches are introduced. The special feature was the part which the pelvic fascia plays in supporting these parts, and that the perineum has little or nothing to do with it. Whenever a condition is seen in which the posterior wall of the vagina is not in contact with the anterior wall, we might be sure that the *fascia* is not in proper condition.

DR. REAMY, of Cincinnati, thought that if this operation was to be substituted for the one so admirably described by Dr. Emmet in his book, it was a comfort to know that he had had an opportunity to undo the great

evil which he had done. He concluded from Dr. Emmet's last explanation, as well as from the paper itself, that Dr. Emmet believed all the perineal tissues down to muscles amounts to nothing. If this is true he should not be surprised to see some child born with all these parts lacking. He asked Dr. Emmet if he had not found any number of superficial lacerations where stretching of the posterior wall of the vagina does not exist, the separation from the deeper tissue is not great, and yet the posterior commissural junction of the labial walls on both sides up to the entrance of the vagina are lying above the circle of the hymen as it exists in the virgin state? He was unable to see how the proposed operation could do more than dispose of redundancy of tissue in the posterior wall of the vagina in a limited number of cases, and could not agree with Dr. Emmet if he recommended it as a substitute for his former operation for this injury.

DR. FRANK P. FOSTER, of New York, denied entirely that the perineum has anything to do with the support of the structures above it, when all the parts are in a normal condition. He thought there was not a single instance in anatomy where an organ rested upon anything beneath it. What the perineum will do, and often does do, but what it does not do normally, is quite another question. But it does not by any means follow that the perineum has no function.

DR. SUTTON thought that any operation for lacerated perineum that did not have for its object the speedy restoration of the perineal body could not stand in the light of the teachings of the last ten years.

DR. EMMET said he expected it would be stated that he had denied the existence of the perineum, although he had endeavored to explain how it was lacerated and drawn to each side like the separation of a curtain. He did not deny the existence of the perineum, but simply denied that any such surface exists as we have been led to believe, and which operators have aimed to build up. He thought the gentlemen would not disagree so much with him as appeared when they could have the opportunity to study his paper leisurely and carefully.

DR. C. C. LEE, of New York, then read a paper on

THE MANAGEMENT OF ACCIDENTAL PUNCTURE AND OTHER INJURIES OF THE GRAVID UTERUS AS A COMPLICATION OF LAPAROTOMY,

in which he gave the details of seven cases of this rare complication—all he could find in medical literature—including one that had occurred in his own practice. From them he deduced the following conclusions:

First.—The pregnant womb may be punctured or otherwise wounded during laparotomy without necessarily causing abortion.

Second.—Miscarriage seems with *a priori* and from clinical evidence to depend upon injury of the uterine contents, not of the womb itself, however severe.

Third.—If the former has certainly occurred, Caesarean section is indicated and should be promptly performed. In this case the utmost care must be subsequently taken to secure thorough drainage from the uterine cavity.

Fourth.—If the uterine walls alone are injured, the wound is to be treated on general principles. If a deep puncture or incision, it must be sutured with the minutest care, with exact coaptation of the edges. For this purpose fine silk sutures, rendered antiseptic, are the best. If a nick or superficial puncture, it must not be ligated, for ligatures cut quickly through uterine tissue; if too small to be sutured, the bleeding points must be lightly touched with the thermal cauterium until oozing has ceased. Good surgery and the dictates of humanity alike demand that under such circumstances a chance of survival be given the child as well as the mother.

The paper was discussed by Drs. Wilson, of Baltimore, Garrigues, of New York, and Byford, of Chicago.

DR. A. REEVES JACKSON, of Chicago, then read a paper entitled

IS EXTIRPATION OF THE CANCEROUS UTERUS A JUSTIFIABLE OPERATION?

The purpose of the paper was to discuss the single question in view of the facts known to us. His conclusions were as follows: He had endeavored to show: 1. That diagnosis of uterine cancer cannot be made sufficiently early to insure its complete removal by extirpation of the uterus. 2. When the evidence can be established, there is no reasonable hope of effecting a radical cure, and other methods of treatment offer far less dangers than excision of the entire organ, and are equally effectual in the amelioration of suffering, retarding the progress of the disease, and prolonging life. 3. Extirpation of the uterus is highly dangerous, and neither lessens suffering—except in those whom it kills—and does not give a reasonable promise of recovery, and should not be adopted in modern surgery.

DR. VAN DE WARKER, of Syracuse, explained how he had sloughed out the uterus by means of chloride of zinc, and exhibited microscopic sections which he believed illustrated that tissue not the seat of cancerous infiltration had been reached. He had operated in this manner in eight cases and with gratifying results.

DR. EMMET, of New York, said that the author of the paper had fully expressed his own convictions concerning this operation. He had opposed the operation from the beginning.

DR. BAKER, of Boston, said he was a believer in the local origin of cancer, and therefore that operative measures were of great advantage. He explained at some length his method of operating without removing the uterus, and several of his patients still lived, now at least five years after the operation was performed, and are apparently well. We thought that sufficiently early diagnosis could be made in many cases as to allow of complete removal of the disease. He thought that the cases in which complete removal—extirpation of the uterus—was justifiable were few in number.

DR. PALMER, of Cincinnati, endorsed Dr. Jackson's paper.

DR. SUTTON, of Pittsburg, thought the operation justifiable, and described different methods of operating, as practised by Schroeder and Martin.

DR. JACKSON, in closing the discussion, said that in performing this operation the operator was like the gambler who stakes what he does not own, the life of his patient against the heaviest of odds.

OFFICERS FOR THE ENSUING YEAR.

President—Albert H. Smith, Philadelphia; *Vice-Presidents*—James R. Chadwick, Boston; Samuel C. Busey, Washington; *Secretary*—Frank P. Foster, New York; *Treasurer*—Matthew D. Mann, Buffalo; *Members of Council*—T. G. Thomas, Fordyce Barker, New York; T. A. Reamy, Cincinnati; R. S. Sutton, Pittsburg; R. B. Maury, Memphis.

The Society then adjourned to meet on Thursday, at the close of the Executive Session.

[To be concluded.]

THE NUMERICAL STRENGTH OF THE PROFESSION IN PARIS.—The *Revue de Thérapeutique* gives an exact census taken of all the practitioners in Paris at the present time. There are in Paris and the communes of the department of the Seine, 1,915 doctors of medicine, 12 doctors of surgery, 83 *officiers de santé* 43 foreign doctors, 1,500 midwives, 845 *pharmaciens*, and 95 veterinary doctors. One of the oldest doctors in Paris is M. Ricord, born in 1800, and made a doctor in 1826. These figures are, of course, exclusive of the host of illegal practitioners of all kinds to be found in Paris.

STATE MEDICAL SOCIETY OF VIRGINIA.

Fourteenth Annual Session, held at Rockbridge Alum Springs, Va., September 4, 5 and 6, 1883.

(Concluded from p. 302.)

THE newly elected President, DR. J. EDGAR CHANCELLOR, of Charlottesville, being in the chair, the afternoon session, September 6th, was opened by DR. S. K. JACKSON, who read the report on

ADVANCES IN THE PRACTICE OF MEDICINE.

He said that although Huxley has dated the advance of medicine as occurring eight centuries ago, scientific medicine can be hardly said to have made much progress until the discovery of oxygen, and showed how much benefit the profession has derived from the young science of biology. By the advancement of the germ theory, the pathology and therapeutics of all diseases of parasitic origin have been revolutionized in the past few years, and the study of the differences between germicides is one of the most important questions of the day in practical medicine. For years mercury has been employed for the destruction of epizoe, but the profession, until within a comparatively late interval, did not know how much good in the destroying of entozoe was being done by its administration. Dr. Jackson proffered the law "that no organism can live in its own excreta—that the products of its life-processes become poisonous to it, stop its ravages, and destroy its life." He believed that it is only as a germicide or antidote that quinine is to be used, without reference to any other therapeutical or physiological quality it may possess. He spoke in favor of Koch's discoveries, announcing his full belief in their practical importance. Concluding, he gave some very interesting mortality statistics of the city of Norfolk, Va., showing the diminution in its death-rate from medical attention.

DR. DABNEY, of Charlottesville, said that "tubercular bacilli" are not yet proven, as the same micro-organisms have been found in many other places. He also instanced the fact that at the Brompton Hospital for Consumptives over fifteen thousand patients were treated in twenty years, and during that time there was no case of tubercular disease occurring among the attendants.

Dr. Wm. C. Dabney, of Charlottesville, read a volunteer paper entitled,

THE PRESENT ASPECT OF THE BACILLUS TUBERCULOSIS QUESTION.

He did not believe in the value of Koch's so called discovery of the bacilli of tubercle, in the face of the contradictory testimony offered by so many other observers. Lichtheim and Cramer have found micro-organisms, behaving precisely like Koch's bacilli with staining fluids, in the fecal discharges of healthy individuals; Spina claims to have found similar organisms in pus from a rabbit's thigh, formed after traumatic injury; Echile has found bacilli in purulent discharge from the ear, and Rosenstein has found them in the urine. Koch says that the bacilli are present in the incipency of tuberculosis, and are its essential cause, while Spina states that they are only found in caseous tubercular deposits that have been exposed to the atmosphere, and do not cause the disease. Koch's experiments have been mostly performed on the lower animals, rats, rabbits, and guinea-pigs, and Dr. Dabney points out the fact that the inoculation of these animals with various substances is liable to lead to caseous inflammation and tuberculosis.

DR. CHAS. M. SHIELDS, of Richmond, read the report on

ADVANCES IN OPHTHALMOLOGY AND OTOTOLOGY,

in the course of which, after dwelling on some of the advances in the physiology of the eye, he mentioned the investigations made in Dr. Hirschberg's clinic, bearing on sympathetic ophthalmia, in which after the enuclea-

tion of four eyes which had been subjected to the operation of neurotomy from two months to four years before, the ciliary nerves were found to have reunited. He thought that neurotomy should not be adopted as a substitute for enucleation unless the patient could be under occasional observation afterward, so that the eye could be enucleated if the cornea again becomes sensitive. The operation of trituration of the cortex of the lens in incipient cataract, to hasten its maturity, was favorably commented upon. The use of antiseptic precautions in cataract was advocated, but the spray of carbolic acid should be used before the operation to disinfect the air of the room. He does not use it during the operation because of its liability to dull the instruments, these latter being disinfected in alcohol. An addition to the therapeutic agents appropriate to the treatment of iritis, is the sulphate of eserine, used after the manner of Dr. Seely to contract the blood-vessels of the iris, while mydriasis is still kept up by atropine. It was also recommended in the suppuration following cataract extractions, the pupil being kept dilated here too by atropine. In peripheral ulceration of the cornea, eserine is becoming popular, and as a treatment for acute glaucoma its merits are better recognized. The electro-magnet for removal of metallic substances from the vitreous and ciliary bodies, the hydrobromate of homatropine for transient dilatation of the pupil for ophthalmoscopic examination, and the value of nitrite of amyl in amaurosis resulting from large doses of quinine were all mentioned at length. Passing to otology and laryngology, the reporter advised sulphide of calcium in doses of from one-sixth to one-fourth grain every two or three hours, in inflammation of the external auditory meatus and furuncles of the meatus. He had also found it useful in mastoid disease, but liberated pus when found to exist. The use of special instruments in removing foreign bodies from the ear was deprecated, as the larger proportion of them could be removed without harm by the syringe. In suppurative inflammation of the middle ear, the dry method of treatment had been found the most effectual. Powdered boracic acid is blown into the canal until it is filled, and kept in place by a bit of cotton, after preparing the ear by cleansing it with borated cotton instead of the syringe; this mode of treatment often curing old cases of otorrhea in two or three applications. The reporter advised the plan of Schalle in treating many cases of nasal and post-nasal catarrh, which is to apply powders of nitrate of silver and calcined magnesia, in the proportions of 1 to 6, 1 to 10, or 1 to 15 parts, to the nasal and post-nasal cavities. He closed by stating his belief that hypertrophic nasal catarrh was never permanently cured, until the redundant tissue had been removed, either by Jarvis' snare or the galvano-cautery.

Upon the conclusion of his paper Dr. Shields exhibited a sample of the new remedy for granular lids and pannus, abrus precatorius, or jequirity seeds, at the same time giving reasons for his belief that the seeds were not such a new article and great rarity as is commonly supposed.

Drs. Parker, Jackson, and White discussed the paper, the latter reading a monograph upon the subject of jequirity, in which he gave the testimony for and against the drug, concluding that its value has been clinically demonstrated to exist, and that it appears as if the profession has in its hands a remedy for that disgrace of eye surgery, granular ophthalmia.

DR. J. A. WHITE, of Richmond, read a volunteer paper on

INJURIES TO THE EYE,

illustrated by reports of a number of cases. So little is said concerning these affections in the text-books, that the detailed cases reported by Dr. White were of extreme interest and value, those illustrative of concussion and compression being especially so. One of the cases was peculiar for the rapidity of blood-absorption in the eye.

The patient, a boy of fourteen years, was struck in the eye by a stone July 1st; treatment by muriate of pilocarpine, for hemorrhage into the vitreous, began on the 4th; on the 6th, the vitreous was perfectly clear from blood; probably one of the most rapid absorptions of the kind on record, as the time occupied is usually from three to six weeks. Another remarkable case was that of a boy twelve years of age, who was struck with great force on the eye when the lids were closed, by a stone from a "gravel-shooter," rupturing the anterior capsule, without cataract following the injury. Dr. White stated that this result was almost unique, he had never seen a similar instance in fifteen years' eye practice. The iris was somewhat torn, and the exuding blood acted as a kind of plug to prevent opacification of the lens substance by the aqueous humor. He concluded with some very practical remarks on the stretching the zonula of Zinn, and dislocation of the lens, with cases.

DR. GEORGE BEN JOHNSTON, of Richmond, presented a report of forty-seven cases of

URETHRAL STRICTURE TREATED BY INTERNAL URETHROTOMY.

He claimed this operation as the surest method of curing stricture in the male urethra. The main features of his treatment are thorough division of the stricture and persistent local treatment for a long time afterward. He stated that many of his cases were re-examined from four months to four years after cutting, and no contraction was found.

DR. W. F. BARR, of Abingdon, chairman of the Committee on Advances in Hygiene and Public Health, did not report in full, but made an apology to the Society in writing, in the course of which he pointed out the facility with which any person is able to practise medicine in the State of Virginia, by the simple payment of a license fee, and mentioned the ineffectual efforts made in past years to procure remedial action from the Legislature.

The Secretary read a preamble and series of resolutions presented by DR. W. G. ROGERS, of Charlottesville, which were unanimously adopted, in favor of the Society appointing a committee to petition the Legislature at its next session to make it a penal offence for any druggist to refill a prescription containing opium, morphia, or any other narcotic poison, for any person, without the special order of a physician to that effect, on account of the influence in producing the "opium habit" and its kindred affections which the habit of indiscriminate prescription refilling, at present so common, has so often brought about.

DR. RAWLEY MARTIN, of Chatham, read a volunteer paper devoted to a description of an

EPIDEMIC OF DIPHtheria IN PITTSYLVANIA COUNTY,

occurring during the summer and fall of 1882. The origin of the epidemic was never found, although carefully searched for, and it seemed to have arisen spontaneously. All the cases were developed either along small watercourses, or near places where rank vegetation was most abundant, although one of the worst cases occurred in a private house, where the best sanitary conditions possible existed, miles away from any point of contagion. Decided croupal symptoms were generally absent, and many cases died after all throat affections had subsided. No adults suffered from severe symptoms, and the children attacked who died were between three and twelve years of age. Nursing children suffered from symptoms of an erysipelatos character. The epidemic subsided as suddenly as it had begun, and was followed by a general outbreak of follicular pharyngitis. A full dose of calomel at the beginning of a sthenic case of the disease invariably modified its course, and alcohol was one of the best remedies in all instances. A number of cases were saved by rectal alimentation. Sanitary conditions seemed not only to be of little use, but where they existed the symptoms were most malignant.

DR. WM. H. COGGESHALL, of Richmond, gave

REITER'S THEORY OF DIPHtheria,

which is simply that the disease is caused by the fibrin-destroying function of the liver not being properly fulfilled, and, as a natural sequence, calomel is indicated for the restoration thereof. Dr. Reiter gives twenty grains at once, and ten grains every hour afterward, until half an ounce of the drug is taken.

DR. BEDFORD BROWN, of Alexandria, read a paper based upon his

THIRTY YEARS' PERSONAL EXPERIENCE IN DIPHtheria.

He thought, from his observation, that two of the gravest symptoms in this disease are the peculiar erratic decline of the heart's action and the almost correspondingly rapid decline in the number of red corpuscles in the blood. His experience has taught him to believe thoroughly in the non-identity of membranous croup and diphtheria. It seemed to him very often that the cases where fever remained when the local symptoms began to abate succeeded the best. He recalled the time when diphtheria was considered a malignant type of a local disease. One of the very great favorites in local treatment then was a mixture of myrrh, creasote, and turpentine. He pointed out the different modes of using mercury. Formerly emetics were given, and then mercury in large sedative doses; in later times we give the latter in small, frequent, alterative doses. Quinine has held favor for use in this disease longer than any other drug, certainly for over a quarter of a century. He thinks that the paralytic effect of the diphtheritic poison on nervous systems can best be retarded by alcohol. He never saw a serious case recover where alcohol was not used. His experience has taught him that if belladonna, ergot, or digitalis cannot stay the paralyzing effect of the poison on the heart through the sympathetic system nothing else will. Such powerful agents as bromine and carbolic acid should be used locally with great caution. Dr. Brown always pays the greatest attention to the digestive organs during an attack of diphtheria, as in every serious case such organs are more or less in a condition of paralysis, and it often becomes a vital question as to how the patient shall procure enough strength from food to support the powers of life. He sustains the patient by means of diffusible stimulants, gives them plenty of fresh air and digestible food, and believes in the great importance of keeping the nose and throat as clean as possible. For this latter purpose he uses with an atomizer, listerine, 1 oz.; aq., 4 oz.; Labarraque's sol., $\frac{1}{2}$ oz.; carbol. acid, 6 drops. Internally, tinct. ferri chlor., 2 dr.; chlor. pot., 1 oz.; tinct. nuc. vom., 20 drops; tinct. digitalis, $\frac{1}{2}$ dr.; aq., 2 $\frac{1}{2}$ oz.; one teaspoonful every two hours.

DR. DABNEY said that he had seen cases occur where excellent sanitary surroundings were present, and was positive that peritonitis had been a sequela of diphtheria in his observation.

DR. S. B. MORRISON, of Rockbridge, never saw a case that was not constitutional in origin, but believed also in the constant use of local treatment. His own observation had taught him that the diphtheritic poison can remain quiescent in one place for years, and then break out suddenly. He thought that all our remedies should be used at shorter intervals in the disease than is the present practice, and that where the vitality of an individual is strong the disease cannot be contracted, notwithstanding full and frequent exposure. He had no doubt but that the germ of typhoid fever and diphtheria was the same, with a different manifestation in each case; and strongly believed in complete isolation of the patient in the latter disease.

DR. ST. PIERRE GIBSON, of Staunton, believed that peritonitis may be produced by diphtheria, citing a case in point; and had no doubt about the fact that the poison of diphtheria may linger in mountain regions for years without sign, and then suddenly become endemic.

DR. A. M. FAUNTLEROY, of Staunton, cited a case to

show its peculiar contagious or infectious properties, which had occurred in his own practice. A child dying from diphtheria at a distance was brought home, its body, packed in ice, lying for a few hours before burial in a room. A day or two afterward a strong, healthy servant-girl cleaned up the floor with warm water, where the ice surrounding the body had melted and dripped, and within a short space of time developed a malignant case of the same disease. In another instance a boy stopped over night at a house where diphtheria had occurred some time before, and the next day entered an asylum for deaf mutes, where thirty-two cases of the disease appeared in a few days. He had often found general disturbance before any appearance of local lesion. He thought local treatment was mainly important, because the membrane present becomes, after a time, putrefied, and, of course, if left alone the putrescent poison would be carried into the circulation by the lymphatics. This was the reason for the local employment of disinfectants. He found one of the most unpleasant concomitants of the disease to be the inability of the patient to ingest food, and instanced one case of recovery where the child was fed for three weeks through a tube. The local application he preferred was a combination of Monsel's solution, carbolic acid, and glycerine, applied with a brush. For internal treatment he used chlorate of potash, large doses of tincture of iron, five-grain doses of quinine, and unadulterated whiskey.

DR. WILLIAM SELDEN, of Norfolk, during forty years of practice, had never known a better systemic form of treatment than the chlorine made from muriatic acid and chlorate of potash according to "Watson's Practice," first edition. Of this he uses one-half drachm to four ounces of water, and has never seen a case die under such treatment. For local application he employs, alum, two drachms; salicylic acid, one drachm; sulphur, one drachm, with enough glycerin to bring the mixture to the consistence of honey, applying with camel's-hair brush. This may be styled the general Norfolk treatment.

Adjournment to 7.45 P.M.

Evening session opened at the time appointed, the President, Dr. J. Edgar Chancellor, in the chair.

Invitations were read from Rockbridge Alum Springs, Blue Ridge Springs, and Rawley Springs, asking the Society to accept the hospitalities of each place for next year's meeting. After full resolutions of thanks had been voted to the Rockbridge Springs Co. for their hospitality of this year (all delegates having been received free of charge during the session), the invitation from Rawley Springs was accepted. An invitation from Alleghany Springs was received too late to be voted upon.

DR. A. M. FAUNTLEROY, of Staunton, read a paper, by invitation, on

THE THERAPEUTIC VALUE OF ROCKBRIDGE ALUM WATER.

He gave a full description of the ten springs located at the place of meeting, and fully described the great value of the water in scrofulotic and syphilitic disorders, the different waters being extremely alterative and deobstruent in their action, and particularly valuable in many instances in dissolving tubercular deposits. In cases of dyspepsia the water of one or more particular springs diminishes the acid secretion from diseased gastric tubules, and in torpidity of the liver it restores the normal activity of that organ, probably through the presence of sodium sulphate held in solution.

The President, DR. J. EDGAR CHANCELLOR, delivered a short address upon the therapeutical employment of the Rockbridge alum waters, enumerating several serious cases of strumous disease in his practice which were entirely cured by their use.

DR. J. MARION SIMS, of New York, Honorary Fellow of the Society, by letter greeted his fellow members, and sent his best wishes for the success of the Society.

DR. J. J. CHISHOLM, of Baltimore, made a few practical remarks on diphtheritic eye troubles.

DR. L. McLEAN TIFFANY, of Baltimore, in the course of his remarks upon

TRACHEOTOMY IN DIPHTHERIA,

stated that in his opinion, while the operation never cures the disease, but simply relieves one oppressive symptom, it never kills the patient. He thought that it is almost impossible to decide just when the difficulty of breathing comes from the top of the windpipe, this indicating the value of the operation. He never had been able to exactly determine when the obstructing membrane was above the sternum and when it was below the common point of opening; and related the particulars of a peculiar case where he opened the trachea just before death, and found the windpipe so completely plugged with diphtheritic exudation that neither a tracheotomy tube nor a probe could enter.

DR. L. B. EDWARDS, of Richmond, mentioned a case where tracheotomy relieved dyspnoea, although the membrane was below the point of opening.

DR. W. W. PARKER, of Richmond, begged the younger members not to become discouraged when they lose a patient from diphtheria, as he did not believe that any physician saves all his cases of that disease.

DR. J. N. MACKENSIE, of Baltimore, stated that one of the after-effects of diphtheria not generally mentioned is adenoid growths in the post-pharyngeal space. He believed that the simplest treatment for the disease is the best, and relied mainly upon steaming for local treatment. He thought the later German topical application (one to two grains bichloride of mercury to one pint of water), was excellent.

DR. R. I. HICKS, of Casanova, mentioned a peculiar instance where a diphtheritic patient associated with many persons in the same locality without the production of another case of the disease.

Drs. Patterson, Whiting, Craddock, and others, discussed the subject of diphtheria and related a number of cases.

DR. S. K. JACKSON, of Norfolk, by request, described his method of preventing

CHOLERA INFANTUM.

He gives the following preparation to any child that is liable to contract the disease: sulphite of soda, hyposulphite of soda, bicarbonate of soda, each 32 grains, aromatic syrup of rhubarb, 2 ounces. One teaspoonful or less, according to age, every two hours each morning, until two or three doses are taken. He claimed never to have had a case of the disease in his practice since using the preparation.

The remainder of the session was occupied in transacting Society business, and after deciding upon malarial fever as the topic for general discussion at the next meeting, the Society adjourned to meet at Rawley Springs, in September, 1884.

There has never before been a meeting, in the history of the Society, so remarkably well attended and so replete with interest and instruction to the members, as that of 1883. Among the visitors present, Drs. Chisholm, Tiffany, and Mackensie, of Baltimore, Md., may be mentioned as having assisted greatly to make the session one of extreme practical value.

The officers elected for the ensuing year were: *President*—Dr. J. Edgar Chancellor, of Charlottesville; *First Vice-President*—Dr. S. B. Morrison, of Rockbridge; *Second Vice-President*—Dr. J. A. Graybill, of Amsterdam; *Third Vice-President*—Dr. Bedford Brown, of Alexandria; *Fourth Vice-President*—Dr. S. K. Jackson, of Norfolk; *Fifth Vice-President*—Dr. J. M. Estill, of Tazewell C. H.; *Sixth Vice-President*—Dr. T. J. Pretlow, of Jerusalem; *Recording Secretary*—Dr. R. B. Cabell, Jr., of Richmond; *Corresponding Secretary*—Dr. Hugh Taylor, of Richmond; *Treasurer*—Dr. R. T. Styll, of Richmond; *Executive Committee*—Dr. W. W. Parker, of Richmond, chairman; Drs. Black, Cunningham, Claibourne, and Gleaves; all other committees holding over.

Correspondence.

SUPPORTS TO THE PELVIC ORGANS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In studying various branches of surgery we are compelled to consider minutely the relations of various organs to one another, and many of them, such as arteries, veins, and nerves, are of great interest, inasmuch as they are directly concerned in many operations, and are the object to be reached or avoided, as the case may be, by the surgeon. Again, we study the relation of organs constituting the thoracic, abdominal, and pelvic viscera, that we may detect with accuracy certain pathological conditions, and at the same time determine the cause and select a method of treatment.

It seems to me that in no branch of surgery is this latter class of relationships so important as in that pertaining to diseases of women.

Do not understand me to say that a derangement in the situation of the pelvic organs is of more moment as regards the life and comforts of the patient than that of any of the thoracic or abdominal organs, but that the importance to the surgeon is in exact ratio with the facility with which abnormalities can be detected and treated, is a matter which I believe is generally appreciated.

Among the many disorders described by gynecologists, and the numerous causes to which they are attributed, there are some which I believe to depend upon conditions which have heretofore been unnoticed, or, if noticed, regarded of such slight value as to have escaped mention. These conditions are involved in the construction, relation, and action of the interfemoral and ischio-rectal regions, the nates, and the obturator internus muscles.

Respecting the ischio-rectal region, we have situated on either side of the rectum the ischio-rectal fossa, bounded internally by the sphincter ani, levator ani, and coccygeus muscles; externally by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the obturator internus muscle; limited in front by the perineal body, and behind by the lower border of the gluteus maximus muscle, and the great sacro-sciatic ligament. Each fossa is filled, in the healthy state, by a mass of adipose tissue of a triangular shape, with its base directed downward and resting upon the integument of this region.

Each mass will measure one inch transversely, one and a half inch antero-posterior, and two inches in length.

Now, when we consider the location, relation, and magnitude of the two bodies, and compare them in these various respects with the perineal body, it is reasonable to suppose that each of the three perform a similar function; but before describing this, I wish to speak of the interfemoral region.

We have covering the adductor group of muscles of either thigh a thick layer of fat, increasing in thickness as it approaches the perineum, and in the well-formed female sufficiently abundant to closely approximate the thighs. It will be noticed also that these accumulations of fat are controlled principally by the adductor muscles, and can be elevated and brought firmly together at the will of the person.

I know of no simpler way of demonstrating the action of these parts, than by calling attention to the phenomenon which takes place in an effort made by an individual to prevent an untimely discharge from the bowels or bladder.

This consists in expelling the air from the lungs, firmly adducting the lower limbs, and rotating them outward. By expelling the air from the lungs, the pressure within the abdominal cavity is diminished.

The adduction of the thighs is a very important act, inasmuch as it presses the interfemoral masses of adipose

tissue firmly together, and upward against the perineum, and having combined with it the outward rotation, produced partly by the lower border of the glutic maximus and the obturator internus muscles, we have the nates brought firmly together and pressing upon the ischio-rectal region. Thus the whole floor of the pelvis is raised, and the organs wedged upward near the brim and against the sacrum. By the contraction of the obturator internus muscles (which means an approximation of its extremities *and an increase in thickness*), we have a pressure exerted directly upon the sides of the pyramidal-shaped mass of fat contained within the ischio-rectal fossa, and indirectly upon the sphincter ani and levator ani muscles, and the capacity of the pelvis diminished.

Through this combination of forces we have a condition produced which relieves the sphincters and the muscles of the perineum from the strain brought upon them by the pressure from above.

The mass contained within the rectum is elevated, the urethra is firmly compressed, and thus an expulsion of either feces or urine prevented.

Now, that we have considered the gross anatomy and physiology of these parts in a healthy state, we can in very few words explain a few pathological conditions resulting from a deficiency of fat composing these supports.

Let us take, for example, a woman somewhat emaciated, or one whose peculiarities of constitution are unfavorable to the accumulation of fat, and we have the supports afforded by the region under consideration to a greater or less degree, and in many cases entirely wanting. The obturators, glutis, and adductors may contract, but the supports from the nates, ischio-rectal, and interfemoral regions are so deficient that they (the muscles) have nothing to act upon, and consequently the muscles forming part of the floor of the pelvis have the whole burden thrown upon them.

There may or may not have been a relaxation of the muscular system, but from the very fact that the pelvic muscles are continually exerting themselves, a lax condition must inevitably follow. Then comes the sensation of dragging and weight in the pelvis. Pain in the back and loins. Rectal and vesical irritation; great fatigue and weakness; leucorrhœa, and other signs of congestion; and later, after the muscles have lost their tone from the constant exertion, we have prolapsus, and the whole catalogue of displacements of the pelvic organs.

Another example of interest is afforded by a subject with a justo-major pelvis. There may be in this case a sufficient quantity of fat, and the muscular system in a state of perfect health, but that the support given by both will be to a great extent lessened will be readily perceived when we take into account the fact that the frequent concomitants of the abnormally capacious pelvis are very long necks to the femurs, giving great breadth to the hips, and carrying the shafts of the femurs, on a level with the perineum, very widely apart.

There is also a large outlet to the pelvis, with diverging rami of the pubes, separating the adductor muscles at their origin. Now, should there be sufficient fat to fill the space between the muscular portion of the thighs, it would be so heavy that, should the person attempt to walk or stand any length of time, the excessive weight would tire and drag down the muscles supporting it, and allow the pelvic organs to settle as previously described. In this way we account for many distressing sensations complained of by apparently healthy and robust women.

In consideration of the foregoing hurried and superficial elucidation of the subject, I trust that in future there may be some attention, at least, given to the support of the pelvic organs by—

First.—The interfemoral adipose pillars.

Second.—The fat of the ischio-rectal region.

Third.—The prominence of the nates.

Fourth.—The physiological thickening of the obturator internus muscles.

As regards the treatment of disorders accompanying

and resulting from a loss of these supports, much depends upon the attention given to the general system.

All pessaries, or artificial supports of any pattern, should be of sufficient size to compensate for the loss of tissue, and yet not large enough to cause pressure of such a degree as to prevent the reproduction of fat.

If possible, a support should be made of vulcanite (hard rubber), from a plaster of Paris cast taken of the vagina while distended, and as nearly as possible in a normal position. A support of this kind will fit accurately, and will consequently be sustained in position by a certain amount of atmospheric pressure.

In case of the justo-major pelvis, the patient will accomplish much by lying upon the back, and adducting the thighs against some power acting as an abductor; such as a spring hoop placed between the knees, or an elastic strap attached to either knee, and to the sides of the bedstead. *Don't apply these forces of abduction below the knees, or you will produce knockknee*; as I came very near doing in one case. By this manoeuvre there is no weight brought upon the floor of the pelvis while the limbs are separated, and by the exercise to the adductor muscles they will become sufficiently powerful to sustain and control the interfemoral adipose pillars.

Very respectfully,

FRANK W. HAVILAND, M.D.,

Late Resident Surgeon Brooklyn City Hospital,
Brooklyn, N. Y.

F 210 WEST 125TH STREET, NEW YORK.

Army and Navy News.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 8 to September 15, 1883.

BARTHOLE, JOHN H., Captain and Assistant Surgeon. Station changed from Fort Lapwai, I. T., to Vancouver Barracks, W. T. S. O. 123, par. 2, Department of the Columbia, September 6, 1883.

BANISTER, J. M., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Adams, R. I. S. O. 170, par. 3, Department of the East, September 10, 1883.

Official List of Changes in the Medical Corps of the Navy for the week ending September 15, 1883.

BEARDSLEY, G. S., Surgeon. Detached from the Galena and placed on waiting orders.

LIPPINCOTT, GEORGE C., Passed Assistant Surgeon. Detached from the Galena and placed on waiting orders.

PERCY, H. T., Passed Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Va., and ordered to the U. S. S. Galena.

BRIGHT, GEORGE A., Surgeon. Detached from Naval Rendezvous at Philadelphia, Pa., on September 30th, and ordered to the Galena, October 1st.

URQUHART, R. A., Passed Assistant Surgeon. Ordered to the Alert on October 6th, and on the arrival of that vessel at Yokohama, Japan, to be detached and to report for duty at the Naval Hospital at that place.

SIMONS, M. H., Passed Assistant Surgeon. To be detached from the Naval Hospital, Yokohama, Japan, on the reporting of his relief, and ordered to the U. S. S. Alert.

TO PRESERVE SURGICAL INSTRUMENTS.—The following formula is recommended by Professor Olmstead, of Yale College. Melt together six to eight parts of lard to one of resin, and stir until it is cool; it can be thinned with coal-oil or benzine. Applied to a bright metallic surface it effectually protects the polish, but the surface should be both bright and dry, as it will not prevent the continuance of oxidation already begun.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending September 18, 1883:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
<i>Cases.</i>								
September 11, 1883. . . .	0	83	36	3	60	21	0	0
September 18, 1883. . . .	0	69	38	3	22	19	0	0

MEDICAL WOMEN FOR INDIA.—The *Indian Medical Gazette* thinks that the project, now being agitated in England, of sending out medical women to India is a visionary one, intended to meet a want which does not exist. Something practical is really being done in India, however. A philanthropic citizen of Bombay, Mr. Kirtledge, has collected a sum of 26,975 rupees, and got the promise of 13,554 rupees more, for the purpose of paying the salary of one or two lady doctors who are intended to have a hospital and dispensary established for them in Bombay, and do their best to obtain practice among native ladies in that city. A wealthy Parsee gentleman has offered a lakh of rupees for the purpose of founding a hospital in connection with this movement, and a large and influential committee, representing every section of the community, has been organized for the purpose of promoting the objects in view.

A STANDARD OF QUALIFICATIONS FOR INSURANCE EXAMINERS.—The medical examiner of "the Catholic Knights of America" says that he will accept no credentials signed by any physician whose diploma is not recognized by the great universities of America. All others will be regarded as incompetent to conduct the examination of applicants to the ranks of these knights. The next question to be determined is, which are "the great universities of America?"

THE COUVREUSE, OR MECHANICAL NURSE.—*The Lancet* gives the following description of the ingenious contrivance known as the *couvreuse*, or artificial nurse. It was in 1878 that Dr. Tarnier, when visiting the apparatus devised by M. Odile Martin, for artificially hatching and rearing chickens at the Jardin d'Acclimatation, suggested that a similar method might be applied with advantage to infants, especially in cases of premature birth. Two years elapsed, however, before any attempt was made to carry out this proposal; but in the course of the year 1880 a *couvreuse* was made, and brought to the hospital of the Maternité. This is a plain wooden case or box, measuring about 2 ft. 8 in. by 2 ft. 4 in., and 2 ft. 4 in. in height. The box has a double covering, the space between being filled with sawdust to retain the heat, and is divided into two parts. The lower half contains a reservoir, which holds about sixty litres of water, and is fed by a patent boiler that stands outside the box, and is warmed by an oil-lamp; or hot water may be used without recourse to the lamp. The upper portion of the box forms a warm chamber, where a little basket or cradle is placed, large enough to hold two infants. From an opening at the side, this cradle may be withdrawn, while the top of the box has a double glass covering, so that the children and the thermometer lying by their side can be constantly

watched. If the water used in the first instance is cold, it takes a long time to attain the required temperature : but once this is done the lamp need only be relit three or four times during the course of the day. It is best to warm the apparatus while the infants are being fed or washed. The temperature within the *couvreuse* is generally maintained at 86° F., and though the contrast on withdrawing the child to be fed or washed is very great, amounting often to 30° F., colds are not so frequent as among the infants nursed in the ordinary manner. Altogether the experiment is considered so successful, that it is proposed to supply all the hospitals of France with a *couvreuse*, and there is every reason to anticipate good results from this measure. Nor is this all. A small portable *couvreuse* is now about to be tried, which could be carried by hand from house to house. After this we shall probably have perambulators constructed on the same model. Although no very careful experiments have been made with respect to the ventilation within the *couvreuse*, yet this is evidently sufficient. Apertures are made in the lower portion of the box, the fresh air travels over the hot-water reservoir, and is thus warmed before it reaches the child. The increased temperature within the *couvreuse* insures a constant current of air, though the child is protected by its cradle and clothes from any draught.

OXALURIA AS A CAUSE OF SPERMATORRHOEA.—Dr. W. H. Dickerman, of Olean, N. Y., sends us the following communication bearing upon the etiology of spermatorrhœa : "While there is a diversity of opinion as to the cause of spermatorrhœa and its local symptoms, it certainly must be conceded that there is an abnormal condition of the nervous system manifested in every such case. Crystals of oxalate of lime are invariably present in the urine of such persons, and as it is generally conceded that free oxalic acid in the circulation is poisonous to the brain and spinal cord, we have a possible cause which should not be overlooked. As an illustration of this condition, the following case is related. A patient, Mr. S. W.—, aged twenty-nine, presented himself for treatment about one year ago. He had been laboring under great mental weakness for several months, and complained of a dull pain and a sense of uneasiness in the occipital region. He said he had frequent nocturnal seminal emissions. There was great irritability of the neck of the bladder, and frequent micturitions day and night. The passage of a sound revealed hyperæsthesia along the prostatic portion of the urethra and at the neck of the bladder. He denied ever having practised masturbation or indulged in excessive venery. He was greatly emaciated. The urine contained in suspension a milky, tenacious, gelatinous substance, and upon microscopical examination many spermatozoa were discovered. Crystals of oxalate of lime were present in abundance. Taking into consideration that in the oxalate of lime diathesis (oxaluria) there is a chronic poisoning of the brain and spinal cord, due to minute particles of oxalic acid in the circulation, I regarded the spermatorrhœa as of only secondary importance, and put the patient upon dilute muriatic acid treatment. In two weeks he returned and said he was well. An examination of his urine confirmed his statement, and he has not been troubled since. As a cure resulted under the acid treatment in so short a time, I was forced to believe that in this case there was no other cause than the oxaluria."

OTITIS MEDIA PURULENTIA AND MASTOID COMPLICATIONS.—Dr. M. E. Alderson, of Russellville, Ky., calls attention to certain cases, primarily of headache and acute pain in the ear, accompanied by discharges, which, as he justly states, do not always receive the necessary careful examination, but are too often dismissed with a few general directions, and thus, after a time, result in serious consequences. In treating these cases, the usual plan by injections of astringent and sedative solutions

he considers to be insufficient. Regarding the radical treatment by trephine, aside from the shock involved, especially in delicate subjects, he finds the results from this procedure by no means certain. The following conservative method is recommended by him, exemplified by the accompanying case : Mrs. —, aged thirty-three, has complained of headache for the past three years, which has become more persistent, until finally recurring every two or three days, and with increased severity. Has been treated for nervous headache by several physicians, and with only temporary relief. Purulent inflammation of both ears had existed for some time, and the external meatus was now covered with layers of thick pus, causing considerable distention and thus adding to the intensity of the pain, which was present on both sides of the head and face, more especially over the mastoid cells. After thorough cleansing with the probe and absorbent cotton, there was discovered by the speculum granulating mucous membrane and fleshy-looking membrano tympani. No polypi existed, and the hearing of both ears was good. For the pain, which was very acute and neuralgic in character, a mixture of aconite and gelsemium was ordered—a few drops q. 4 h. Locally, the entire external canal was packed with powdered boracic acid, previously mixed with calendula and carbolic acid, and thoroughly dried, the whole then being covered with absorbent cotton. This was allowed to remain for three days. The packing was then removed, the canal carefully dried, and the application renewed. To the mastoid process a fly blister was also applied once a week and kept discharging freely. Under this treatment amelioration of all the symptoms followed, and the final results were entirely satisfactory.

FILTH DISEASES IN RURAL DISTRICTS.—Dr. A. L. Carroll, of New Brighton, N. Y., writes : "Sir : On my return from Europe, my attention has just been drawn to a paper by Dr. George Hamilton, published in your issue of July 28th, commenting upon an article of mine on 'Filth Diseases in Rural Districts.' I have apparently been so unfortunate as to fail to make myself understood by Dr. Hamilton, or even to attract his careful reading ; for I cannot discover in my own article the words which he places in quotation marks, nor do I think that many of my statements legitimately bear the interpretation which he gives them. I have no desire, however, to enter upon a controversy touching the etiological researches which abound in English sanitary literature, or the occasional difficulties of diagnosis which all vital statisticians and registrars deplore. My only present object is to clear myself from the totally unwarranted imputation of making a 'thrust at the country physicians.' If Dr. Hamilton will honor me by again referring to my article, he will see that I made the more comprehensive statement that 'very few physicians in this country' have cared to learn the methods of sanitary inspection ; and the context will show him that the fault is imputed to our medical schools, most of which utterly ignore the teaching of hygiene, and graduate family practitioners well qualified, it may be, to treat disease after it has arisen, but without instruction how to detect the insanitary conditions under which their patients may be living."

THE CHAMPIONSHIP OF AMERICA IN TONSIL-CUTTING does not belong to Indiana, says Dr. Tauber, of Cincinnati, O., but to New York. It was stated to me that Dr. Lewis Elsberg, of New York, has excised more than 11,000 tonsils ; this would be, according to Dr. William's calculation, over two and one-half bushels.

TWO CASES OF ABSINTHE POISONING.—Dr. Albert S. Adler, of Lordsburg, N. M., writes : "A few nights ago I was called upon to attend two individuals who had been drinking heavily, and were now in convulsions. Hastening to their place of abode I found that one of the patients, a woman, in an epileptiform convulsion—uncon-

scious, small pupils, and frequent and small pulse. The other was also unconscious, but not then in spasms. All questions in regard to poisoning were altogether refuted by the other inmates of the house. I was about to resort to some stronger means in order to relieve their sufferings, when the young girl, returning suddenly to complete consciousness, claimed that she and her male friend had partaken of over a quart of some alcoholic liqueur, the principal part of which was absinthium. The epileptic convulsions had commenced half an hour prior to my arrival, and, as before stated, lasted in the girl but a short time during my presence; they had been more vehement and frequent in her because she had taken a larger quantity. The man was restored to his senses by slapping his face with wet towels. These cases of epilepsy are of more frequent occurrence than generally supposed. Magnan ('De l'alcoolisme, des divers forms, du delire alcoolique,' etc, Paris, 1874, and 'Annal. Médic. Psych.,' 1874, p. 302), was the first to describe the danger of absinthe drinking. His experiments on animals, as well as observations on man, have demonstrated that it was not the alcohol which brought forth the spasms, but that the absinthium was the source of the vehement symptoms. Alcohol occasions delirium and tremor, absinthium these two and epilepsy in acute alcoholism. Small doses of wormwood given to animals have the effect of producing tremor of the muscular system, dizziness, and in a surprising manner upstarts of individual muscles, in larger doses a complete formed epilepsy. In man, besides the alcoholic delirium, epilepsy is noticed. Among three hundred and seventy-seven persons addicted to the use of alcohol, Magnan found, in 1870, but thirty-one epileptic cases, and in 1871, among two hundred and ninety-one, only fifteen. In France it is regarded by the legal authorities as a poison, and only allowed to be sold in drug-shops. Magnan comes to the conclusion that if epileptic attacks happen in acute alcoholic-poisoning, it was only in absinthe drinkers, and that acute alcoholism without epilepsy, but with tremor of any degree, was but seen in persons partaking freely of wine or whiskey."

A NEW BOARD OF HEALTH has been appointed by the city council of Cincinnati, O. There are six members. Five are saloon-keepers, and the sixth is a so-called doctor, a frequent patron of the saloons, advertises to cure the opium habit, restore lost virility, etc. The Cincinnati *Lancet* is unable to see why so much medical wisdom was injected into the board.

TWO CASES OF ANEURISM EXHIBITING UNUSUAL PHYSICAL SIGNS.—Dr. W. S. Cheesman, of Auburn, N. Y., sends us the following: "While an *interne* in Bellevue Hospital, I had under observation, for some three months, a case whose history was as follows: Patient, a man, aged forty-nine, well muscled, and apparently hearty. Contracted syphilis in 1865. In October, 1878, he strained his back while lifting, but recovered. About three months later he over-indulged in liquor, etc., and pain in the back shooting around the abdomen and down the thigh commenced, and in a day or two he observed a pulsation in the abdomen. All these symptoms persisted. About a year later he detected a swelling behind the episternal notch, which caused pain and dyspnoea. He soon suffered from dizziness, pain in the head, flashes before the eyes, and some difficulty in swallowing. As will be at once supposed, these sets of symptoms had separate causes. Repeated physical examinations made it almost certain that the patient had two aneurisms, one of the lower thoracic or upper abdominal aorta, the other of the innominate, each giving rise to its own physical signs. The aneurism of the trunk imparted an irresistible heaving impulse to the lower part of the left chest, over which area a low, blowing murmur was heard. The aneurism of the neck was palpably evident behind the right sterno-clavicular articulation as a pulsatile tumor, over which a blowing sound was heard loudly. It gave

rise to much inspiratory stridor, a pressure-effect purely, the laryngoscope revealing nothing abnormal to account for it. An occasional cough had the aneurismal note, but the voice was natural. A curious pulsation was occasionally communicated to the larynx and the tongue. Every now and then the thyroid cartilage would rise and fall synchronously with the pulse of the aneurism, and when at these times the patient opened his mouth, the tongue was seen to pulsate backward and forward. How this motion was imparted to these organs was never ascertained. On auscultation of any part of the chest, one could hear a loud ronchus during expiration, which ronchus intermitted, the intermissions corresponding to the cardiac diastole. It was supposed that pressure on the trachea or a bronchus was made by one of the aneurisms, that this pressure was increased by the contraction of the thoracic cavity during expiration, and that the calibre of the air-tube was so much lessened at the acme of the aneurismal expansion, that a momentary ronchus was then produced. The patient improved, and was finally discharged at his own request. He re-entered hospital four months later, remaining a week. The physical signs were unchanged.

"On June 30, 1883, a laborer, aged forty-three, applied to me for relief of a hoarseness of three months' standing. He was nearly aphonic, and there was much dyspnoea. The laryngoscope showed the left vocal chord paralyzed in abduction. The right chord crossing the middle line in attempts at phonation occasionally met its fellow, and sound resulted. Looking down the trachea, there was distinctly apparent, near its bifurcation, a pulsation which narrowed the lumen of the tube, and at the same time moved it somewhat from left to right. Over the upper sternal region a small area of dulness was made out, and here a double blowing murmur could be heard. The heart was displaced downward and to the left. A thrill was felt in the subclavians. The cough was markedly aneurismal. No history of syphilis or strain. Aneurism of the arch compressing the trachea was diagnosed, and a gloomy prognosis given. Both opinions were verified about a month later by the patient's dying suddenly in the night with a tremendous hemorrhage. I regret that in my absence from the city no post-mortem was made. The physical signs which gave these cases their interest, and which I have not hitherto seen described, were: 1st, the pulsation upward of larynx and tongue; 2d, the intermitting ronchus in Case I.; and 3d, the pulsation observed near the bifurcation of the trachea in Case II."

IMPURITIES AND ORGANISMS IN THE AIR OF THE COMPRESSED AIR-CHAMBER.—In a communication addressed to THE RECORD, Dr. Arthur J. Wolff, of 66 Capitol Avenue, Hartford, Conn., late A. A. Surgeon, U. S. A., calls the attention of all who have occasion to use compressed air for the propulsion of various substances into the air-passages, to the danger thereby incurred of forcing disease germs into those organs. He states on the strength of experiments recently conducted by him that: 1. By the use of the compressed air-chamber, as at present constructed, we cannot avoid the access of impure air to the throat and air-passages. 2. The confined air-space affords the most propitious conditions for an enormous increase of the various spores, bacteria, fungi, etc., contained in the air of the room from which the supply is derived. 3. The mere mixture of this air for a short time with any solution that may be used in the spray apparatus, even having the most perfect antiseptic qualities or being in itself eminently a microbicide, is insufficient to sterilize it. 4. The use of this air is in itself, in certain cases, effective in producing an increase of the throat trouble. The author demonstrated the existence in the air-chamber of carbonic acid and chlorine in large quantities, when the air from a room in which these gases had been liberated was pumped into the receiver. The presence of micro-organisms was deter-

mined by the following experiment: Having brought the pressure in the condenser to indicate thirty-five pounds, he slowly passed the air through a series of three bottles, the sides and bottoms of which were smeared with glycerine. The glycerine being then removed and placed under the microscope, the presence was discovered of a great number of spores of cryptogams, bacilli, bacteria, micrococci, pollen of certain plants, indeterminate masses, and mineral particles. He discovered one variety of microbe in particular, about $\frac{1}{65000}$ th of an inch in length, which resembled the bacillus tuberculosis very closely in appearance and in the peculiarity of staining. The author proposes in subsequent experiments, by isolation and cultivation according to Koch's method, to determine the question of the identity of this bacillus with that which the modern theory recognizes as the cause of tuberculosis. He showed by further tests that the air was not purified by passing through the supply tube containing various antiseptic solutions, such as iodine, mercuric chloride, zinc chloride, quinine, etc. Dr. Wolff concludes with a description of the method employed by him to sterilize the air before it passes into the condenser. He passes it through a series of U-tubes filled with fine iron wire heated to redness. It is subsequently conducted through a bulb, loosely packed with absorbent cotton saturated with a solution of corrosive sublimate (1-500), and is then ready for use. The large measure of success which he has met with in the treatment of diseases of the respiratory organs he attributes in great part to the precautions taken to force only purified air into the air-passages. It is his desire to present these facts to the profession in order that they may receive thoughtful consideration, and that others may be led to adopt greater precautions to guard their patients from the probable dangers of the compressed air apparatus.

THE AMERICAN MEDICAL COLLEGE ASSOCIATION.—The *Southern Practitioner* reports the death at Nashville, Tenn., on the 20th ult., of the American Medical College Association. It announces the cause of death as "The Bellevue Stab." This reference is, evidently, to the famous advance and precipitate retreat of Bellevue Hospital Medical College, a couple of years ago, on the question of an advanced standard of medical education. Bellevue was loud in her demands for a higher standard, and in the fulness of time went up to possess the land. But she soon discovered that she had been too previous, as it were. She is of "the-old-flag-and-an-appropriation" style of patriot, and was loud for advance as long as the cry seemed popular and was likely to draw students. When, however, the students refused to follow, she quickly sounded the retreat, and thus, as our contemporary intimates, gave the death-blow to the movement to improve medical education in this country. But it is cruel to open these old sores, and more especially at this time, when Bellevue is so faithful to the Code of Ethics. Her new announcement flies the ethical colors on her mast. How long, in the light of past experience, will they thus ostentatiously fly? The size of her next year's class may have an effect in determining the answer to this question.—*Medical Age*.

LONGEVITY IN THE DIFFERENT STATES.—A student of the reports of the tenth census has compiled a table for the Boston *Commonwealth* for the purpose of showing in what State or States one has the best chance for a long life. New Hampshire seems to him to be the favorite refuge of green old age, for he finds that one-seventy-fourth of the inhabitants are at least eighty years old. The proportion among native white males is 1 in 80, but the environment in New Hampshire seems to have been even more favorable to the preservation of life in the other sex, for the proportion among native white females is 1 in 58. Other New England States do not contain quite so many old persons, the average proportion for the six being 1 in 134. Coming to New York, he finds that

for one person who has reached the age of eighty there are 161 who have not been so fortunate, and in the three Middle States the average proportion is 1 in 182. As he goes southward he discovers a greater preponderance of young blood, for in six South Atlantic States the average proportion is 1 in 203. The Gulf States afford a less attractive shelter for the aged, for the average is 1 in 300. In Texas, where so many worthy persons die with their boots on in the prime of life, only one octogenarian can be found in a group of 497 citizens. The average rises again in the interior States east of the Mississippi, but in the great lake States it falls to 1 in 263, a good old age being attained with the greatest difficulty in the wealthy and prosperous State of Illinois. In seven States west of the Mississippi River the aged rarely appear, for the average proportion is 1 in 453. In Iowa a crop of 334 persons yields only one who has reached the age of four-score; in Minnesota, Nebraska, and Kansas only one of these aged citizens can be found in a group that would yield two in Iowa, and in Colorado 1,150 inhabitants must pass in review before an octogenarian comes in sight. The old are even more rare in Nevada, but in California and Oregon the proportion is nearly 1 in 500. If the inhabitants of the whole country could be assembled in two hundred and twenty-seven groups, it would be possible to place at the head of each group one patriarch of eighty or more years. So our student, assuming that long life is the inalienable right of those who reside in New Hampshire, Vermont, and Maine, cries: "Flee to the mountains of New England for health and longevity!"

ITALIAN ENGLISH.—The proprietor of the Hotel de Bellevue at Pompeii, as a means of attracting English custom to his house, has issued an advertisement couched in the following extraordinary terms: "That hotel open since a few days is renowned for cleanness of apartments and linen, for exactness of service and for excellence of the true French cookery. Being situated at proximity with regeneration, it will be propitious to receive families whatever which shall desire to reside alternately into this town to visit the monuments newly found and to breathe thither the salubrity of the air. The establishment will avail to all the travellers visitors of that sepulchral city and to the visitors (willing to draw antiquities) a great disorder and expensive contour of the Iron-whay. People will find equally thither complete assortment of strange wines, and of the kingdom, hotel and cold baths, stables, and coach-houses, the whole with very moderate prices. Now all the application and endeavors of the host will tend always to correspond to the taste and desires of their customers, which will acquire without doubt to him into that town the reputation whom he is ambitious."—*The Caterer*, London.

TO DISINFECT WATER FOR HYPODERMIC USE.—A sure but, so far as we are aware, little practised method for disinfecting water for hypodermic use is to boil it. It is not sufficient that the water be boiled when the hypodermic solution is made for the case bottle; it should be boiled on the spot. The requisite amount is put into a teaspoon, a lighted match is held under it, and the fluid injected while warm. If the practitioner prefers, as many do, to make the solution p.r.n., the required amount of the drug or a pellet may be placed in the spoon, reduced to a powder—better still placed in the water and reduced—and the heat applied, the increased temperature favoring the solution. In this manner bisulphate of quinine may be used without any acidulous accessory, and without the unpleasant effects so often seen after hypodermics of quinine.

OIL OF WINTERGREEN (salicylate of methyl) diluted with an equal quantity of olive oil or soap liniment, applied externally to the joints affected by acute rheumatism, gives prompt relief, and, from its pleasant odor, is very agreeable to use.—*The Quarterly Therapeutic Review*.

THE RECOGNITION OF CEREBRAL COMPLICATION IN AURAL AFFECTIONS, BY MEANS OF THE OPHTHALMOSCOPE.¹

By J. A. ANDREWS, M.D.,

NEW YORK.

CASE I.—*Otitis media purulenta chronica; abscess of middle lobe of cerebrum; death.*—G. J.—, house painter, aged twenty-four, had scarlet fever when twelve years old, since which time he has had more or less purulent discharge from his ears. While descending a ladder, December 18, 1878, pain developed suddenly in his right ear and corresponding side of the head. On reaching home, he went to bed; during the night he vomited; he thought it was an attack of fever and ague. Next morning he was dizzy and vomited. Took gr. xv. of quinine in the morning; at noon he felt worse and sent for his physician, who prescribed Kalium brom. for the head symptoms, and ox. cerium for the vomiting; in the evening of the same day the doctor's attention was attracted to the patient's ears, because of pain referred to depth of right ear. Temperature, 103° ; pulse, 100; resp., 30 per minute. I saw patient three days subsequently: he was conscious and talked intelligently. H. D. R. E., watch ad concham; acumeter, 1"; L. E., watch ad concham; acumeter, 4"; quite deaf for conversation. R. E., slight purulent discharge; drum membrane has a small perforation in its antero-inferior part; calibre of external auditory canal much lessened in consequence of swelling of its lining tissues. L. E., no discharge; no evidence of active disease in this ear. *Double optic neuritis.* R. E., counts fingers at six feet; L. E. V., $\frac{2}{3}$ %. December 24th, saw patient at 9 P.M.; two hours previous to my visit his condition had assumed a marked change; the pain in the right side of the head was intense; he vomited; temperature, 101° ; pulse, 110 and very feeble; he was drowsy, and passed his urine involuntarily; easily roused from drowsy state, when he conversed rationally. December 25th, 2 P.M., patient died in coma. No paralysis, no convulsions.

Autopsy.—Right external auditory canal filled with healthy-looking pus. Extending from the tympanic portion of the Gasserian fissure outward into the external auditory canal for four mm. but not involving the ossicles, the bone was ulcerated. The communication with the brain was made at the point of ulceration just referred to, this being effected through a small fissure in the centre of the ulcerated bone. The dura mater overlying the ulcerated bone was also ulcerated and separated from the bone by offensive-smelling pus; pia mater congested and numerous ecchymotic foci; the middle and anterior fossæ contained pus; brain normal in consistence. Encysted abscess in middle lobe of cerebrum; brain surrounding abscess cedematous; sinuses and internal ear normal. These conditions refer to the right side of the brain. The left temporal bone was not dissected, but there were no changes in the meninges overlying the temporal bone on this side.

Patient's mother informed me that two years after the scarlet fever he took cold in his ear and suffered a great deal with his head. He had headache at times for

several years. Inasmuch as the abscess was encapsuled, and death occurred a few days after the development of cerebral symptoms, we may justly refer the interval of ten years between the attack referred to by his mother and December 18, 1878, as the period of latency.

The above case is an exception to the law which Toynbee endeavored to establish, *i.e.*, that each of the centres of the ear had its peculiar division of encephalon to which it communicated disease: inflammation of the meatus audi. ext. extending to the lateral sinus and cerebellum.

CASE II.—*Otitis media purulenta chronica; optic neuritis; phlebitis sinus lateralis dextra; meningitis of convexity; death.*—P. H.—, aged forty-two, clerk, had had purulent discharge from both ears for eight years, which had never been treated. Three years ago there appears to have been an acute exacerbation and he was treated for inflammation of the brain, but the ears received no attention. Since this attack, patient states that he has enjoyed good health, but, on close questioning, I elicited the fact that for some time after the acute exacerbation referred to, he had headache, which was generally so slight that he did not think it was "significant." July 5, 1879, I was requested to see him. He had been confined to the house for two weeks, during which time he had been very irritable, and had severe pains in the head; the headache was diffused, and at times referred to the right side of the head. There had been no paralysis, nor convulsions, but he vomited during first week of his present trouble. For the first two days he had illusions and delirium; temperature had not been above 100.5° F. On occasion of my first visit I found patient suffering with severe diffuse pain in the head; purulent discharge from right ear; discharge very offensive; removal of the discharge revealed bottom of the canal filled with granulation tissue; right optic neuritis; left disk hazy, veins large and dark-colored, but not tortuous. R. V. = $\frac{2}{3}$ %; L. V. = $\frac{2}{3}$ %. Intensely sensitive induration extending in course of right internal jugular vein.

July 6th.—Swelling of the neck very marked; face puffy. Right processus mastoideus not sensitive to the touch, but patient was rendered dizzy and confused by a light tap on this part. Chills four times during day.

July 7th.—The right mastoid was entered, no pus found, but there was a sharp hemorrhage which stopped spontaneously. He expressed himself as relieved by the operation and slept for three consecutive hours after it.

July 8th.—Puffiness of the face much diminished; temperature at 9 A.M., 101.3° F.; pulse, 95; respiration, 20 per minute. 2 P.M.: temperature, 103° F.; pulse, 95; respiration, 26 per minute. 9 P.M.: temperature, 104.2° F.; pulse, 110; respiration, 32 per minute.

July 9th.—Suddenly he became unconscious, and death occurred in coma. No convulsions.

Autopsy.—All the sinuses contained some fluid blood; right superior petrosal and lateral sinuses contained red coagula, loose in superior petrosal but adherent in lateral sinus. The venous wall of lateral sinus on right side is thickened, its surface brown in color and the bony wall separating the sinus from the mastoid cells is ulcerated at three different points at which offensive smelling pus was seen between venous and perforated osseous wall. Right internal jugular vein contained a disintegrated thrombus. The tegmen tympani was very thick. The dura mater covering tegmen tympani and the adjacent portion of bone on right side was deeply congested, and

¹ Read before the American Otological Society, July 17, 1883.*

numerous small red points (hemorrhages) were seen. This condition was confined to the parts just mentioned and was not evident in any other part of the dura mater. Subarachnoid space and meshes of pia mater covering convexity of cerebral hemispheres and upper surface of cerebellum contains a moderate amount of sero-purulent exudation; the exudation extended down sides of brain and most abundant on right side, but at the base of the brain it was less abundant. The mucous membrane of tympanic cavity was swollen, tumefaction extending into the mastoid cells.

CASE III.—*Otitis media purulenta chronica; meningitis, optic neuritis; recovery.*—J. E.—, aged nineteen, has had purulent discharge from left ear for eighteen months. Short and stout in stature, strumous scars on face directly in front of left ear, also on neck of corresponding side. Right ear has never discharged. He had never been under treatment for his ear trouble. The discharge from the ear has been profuse until about a week ago, since which time it has been scanty. I saw the patient November 16, 1880, six days after the development of threatening symptoms. The left ear contains a large polypus springing from the superior surface of the external auditory canal, at about the junction of its cartilaginous and bony portions. Removal of the polypus, which was very vascular and had a broad attachment, showed the bone beneath to be exposed and rough. There were also two polyps springing from the tympanic cavity; these had such a slender pedicle that they came away while the snare was being applied. Their removal revealed pulsation at the bottom of the canal, and after repeated efforts with the catheter pus was blown through the perforation in the membrana corresponding to the point where the pulsation was noted, but, owing to the swelling of the canal, the perforation could not be seen.

Pharynx very much congested, and secreting thick mucus. Left membrana tympani was incised, considerable pus coming away, much more than was expected from the appearance of the drum membrane, which did not appear bulged forward in any part that was visible. Mastoid process red and painful. Severe headache; the pain was general, but at times it was most severe on left side of head and in forehead. Temperature 101° F.; pulse, 85 per minute. He was very restless; he vomited half an hour before I visited him. He complained of not seeing a certain picture on the wall. Left eye, marked optic neuritis; right eye, retinal veins enlarged but not tortuous, disk very red but not cedematous; no other change in fundus.

An incision over left mastoid showed the bone to be inflamed but firm. No improvement followed this operation, and thirty-six hours subsequently the mastoid was bored into; a small amount of blood, with a trace of pus, escaped from the opening. The cortical plate of the mastoid was very thick. A warm solution of kalium permanganatis injected into the external auditory meatus readily escaped through the opening in the mastoid, which passage I kept free by means of a drainage-tube. There could be no doubt in regard to the immediate result of the operation. He recovered from the influence of the ether rapidly, and in half an hour afterward fell into a quiet sleep which lasted for nearly four hours. On awakening there was less headache, and patient asked for some warm milk, of which he partook with relish.

November 18th.—Patient passed a quiet night; his sleep was interrupted, but he did not suffer from pain in the head. Temperature, 100° F.; pulse, 80 per minute. There is a free discharge from mastoid. I did not examine patient's eyes the morning following the opening of the mastoid, but I did so on the morning of the fourth day after the operation. The left disk was less cedematous and the veins less full and not so dark looking, but the improvement was not striking.

December 6th.—Patient has been steadily improving; there is only occasional headache, and then very slight. There is a marked change in the appearance of the left

optic disk; it is only slightly obscured, but the retinal veins are still fuller than normal. The right disk is now swollen and the veins are large and tortuous.

Patient passed from my care in February, 1881, about two months and a half after the beginning of the trouble. The left optic disk was then hyperæmic, the veins much less in size than when seen two weeks previously; the opening in the mastoid was closed. There was still a slight discharge from the ear. Right nerve is still somewhat obscured, but its improvement is very manifest. The patient was absent from New York until May 2d. I saw him on the 4th; the discharge had ceased since March. The left optic disk appears normal (?), the right disk is slightly hyperæmic. R. E. V. = $\frac{2}{3}$; no improvement with glasses; L. E. V. = $\frac{2}{3}$; right visual field normal; left visual field slightly contracted.

I have intentionally omitted many of the details of this case, and record only what I considered the essential features. The diagnosis of cerebral complication was believed to be confirmed by the ophthalmoscopic examination. I saw the patient for the last time in December, 1881. At that time there was, I thought, no abnormal change in either fundus, but the visual field of the left eye, therefore, on the same side as the ear affected, was slightly contracted.

CASE IV.—*Otitis media purulenta chronica; abscess of the brain; death.*—In the early part of the summer of 1879, Mrs. K.—, aged thirty-one, consulted me on account of distressing subjective noises in her right ear, and difficulty of hearing. At the bottom of the right external auditory canal were two medium-sized polypi; immediately in front of these growths the posterior and superior surfaces of the canal were ulcerated for a considerable extent outward. The left drum membrane presented the appearance of having been the seat of a perforation. She stated that she had had a purulent discharge from the right ear for about thirteen years; there had been a discharge from the left ear, but this had ceased spontaneously after a few weeks' duration. She suffered pain at times in the right ear. I advised the removal of the polypi; but when she was told that the discharge from the ear would not stop so long as the growths were allowed to remain, she seemed rather agreeably surprised, and said: "Why I have always been told that it was not right to stop a running ear." She further told me that during the past winter she had lost her young son, then living in New Jersey, who was said to have died of inflammation of the brain. I asked if he had had any ear trouble, and she replied, "Only a running." This had followed scarlet fever and had, at the time of his death, existed nearly two years. "But," she said, "I was advised to let it alone." In regard to her son's condition just before death, I elicited the following: "The boy complained of pain in his head [ear?] for several weeks before his death; he was unconscious for three days before he died; a blister was applied behind his ear, but this part [mastoid?] was so sore that poultices were ordered." This case seems plainly to have been one of middle-ear disease, terminating fatally from extension to the brain.

Mrs. K.— consented to the removal of the polypi, and this was followed by quite active inflammatory reaction, which, however, was promptly subdued by local depletion, etc. There were no visible changes in the optic nerve. After eight days' treatment she went to Chicago; I therefore lost sight of her until soon after her return, in November, 1879.

December 2d I was requested to see her. On her way from Chicago, three weeks before, she took a severe cold; she had had almost constant pain in the head for upward of two months, especially severe for the past five days, and was referred to the right side of the head. Facial paralysis had occurred on the right side, and there was vertigo. I found her suffering violent pain in the right side of the head and at the depth of the right external auditory canal; offensive purulent discharge es-

caped from the right ear. Vomiting; temperature, 102.8° F.; pulse, 95. Mastoid not tender on pressure, nor does percussion cause vertigo or pain. There is beautifully developed neuro-retinitis in right eye; no changes in left eye; counts fingers at about ten feet with right eye.

5th.—Patient is delirious.

7th.—Patient comatose; no convulsions. She died after having lain in coma for six hours.

Autopsy.—Corresponding to the point of ulceration in the external auditory canal, referred to above, a sinus was found extending into the antrum mastoideum. The roof of this cavity was destroyed by caries; pus to the amount of half a fluid ounce lay upon the carious bone. The dura mater overlying this collection of pus was very much thickened, but not perforated. In the right hemisphere of the brain a large abscess was found, filled with greenish thick pus; the surrounding brain substance was oedematous, but not disorganized; the abscess was encapsuled, but had ruptured into the brain, in all probability only a short time before death. The sinuses contained dark-colored blood, but no clots. The right lateral sinus was unchanged.

The foregoing cases have been presented, not because they exhibit any remarkable or unusual features that have not already received notice in literature, but they are offered more with the intention of eliciting discussion on a subject bearing upon which the writer does not find much satisfactory data in literature.

The cases of cerebral abscess tabulated by Gull, Rudolph Meyer, Wreden, Lebert, and others, furnish no facts which enable us to judge of the frequency or actual presence of signs of intra-cranial disease by the appearance of the fundus oculi. In the majority of instances in which reported cases of cerebral diseases, secondary to an aural affection, appear in literature, the eye is merely incidentally alluded to, *i.e.*, the state of the pupils, the presence of photophobia, or the condition of the sight. In many instances the question of an intra-ocular lesion was dismissed with the observation that the vision was $\frac{2}{3}$. The writer believes that most ophthalmologists will endorse the statement that optic neuritis and central vision $\frac{2}{3}$ are not incompatible. I have seen such cases, and I have now under my notice the case of a physician with advanced atrophy of the optic nerve, and central vision $\frac{2}{3}$, but whose visual field is very much contracted. Then again, when the ophthalmoscope has been used, the record reads: "One or both optic disks appeared obscured and the vessels enlarged." Now the writer believes that it is just such cases that should excite our suspicion of an intra-cranial complication in ear disease—especially purulent otitis media—in which other signs of extension of the trouble to the brain are obscure.

To what extent, in the cases under consideration, an oedema of the optic disk should influence our mode of treatment in regard to an operation upon the mastoid is, in the absence of sufficient evidence, necessarily an open question; but from a careful study of cases in which the mastoid has been opened, the operation does not appear to be a dangerous one when intelligently performed; and the writer would, without waiting for pronounced neuritis, accept the condition of the oedema of the optic disk in the cases under discussion as an indication for opening the mastoid; and if not with the expectation of liberating pus, at least to establish free drainage from the middle ear. The procedure is certainly consistent with a good surgical principle and is not likely to add to the pre-existing mischief.

Not until quite recently has attention been directed to the importance of examining the fundus oculi in aural affections. Allbutt, Kipp, Knapp, and Zaufal are the pioneers in this valuable work of furnishing evidence of the importance of an ophthalmoscopic examination in the class of cases under consideration. Allbutt¹ and Kipp²

have each reported two cases of otitis media purulenta with optic neuritis, in which recovery took place, and Zaufal³ has also recently recorded a case of a student, sixteen years of age, with purulent otitis media, and optic neuritis, which latter condition was observed to rapidly recede after trepanation of the mastoid, and the patient made a good recovery.

Acute otitis media does not commonly prove fatal; the pain in and about the ear often being so intense as to almost completely obscure the symptoms of any brain complication which may exist. The patient generally recovers from the acute symptoms, and there may remain impaired hearing and a purulent discharge from the ear, which latter may continue, if not treated, for weeks and months, and even years, when an acute exacerbation occurs, and the patient dies with the post-mortem evidence of abscess of the brain; the abscess, in many instances, having been formed at the time of the first attack of ear trouble, some years previously. This was evidently the fact in Case I., cited above; however, this is not an isolated case. Otological literature abounds with records of cases of cerebral abscess, which exhibited a long period of latency. In acute abscess there is, as a rule, little or no period of latency, and the disease ends fatally in a few days, the abscess in such cases not being encapsuled. Meyer⁴ states that the earliest appearance of a capsule is at six or seven weeks, and Huguenin demonstrated distinct evidence of the capsule not earlier than twelve weeks. The chronic abscess is characterized by a prolonged period of latency, which intervenes between the early congestive stage and that of the development of the purulent formation. Often the latency is interrupted by a slight degree of headache, which symptom obtained in Case I., and is often confounded with digestive disorders, and escapes scrutiny on that account. The duration of the latency varies from a few weeks to several months.

As far as I have been able to ascertain, the longest attested duration of brain abscess is that case observed by Härlin,⁵ in which the traumatism occurred twenty-six years before death. In another case, reported by E. Schott,⁶ abscess of the brain followed an injury sustained twenty-one years before. In the first case cited in this paper the abscess had, in all probability, existed ten years. The period of latency once being disturbed, the end of the disease is soon reached. Headache was the initial symptom in two-thirds of Meyer's cases of abscess of the brain, therefore somewhat more frequent than in brain tumors, where, according to Ladame,⁷ it ushered in the phenomena of the disease in one-third of the cases.

The intensity of the headache varies greatly: in one case it is almost unnoticeable, in others it excites excessive complaint by the patient. Generally it increases with the duration of the disease, and is more continuous and occurs less in paroxysms than the headache of brain-tumors. The headache is sometimes accompanied with fever, but this is very often absent, even in the terminal stage. A case reported by R. Deutschmann, in a recent number of Graefe's *Arch. für Oph.* (Bd. xix., Abth. i., 1883, p. 292), is a striking illustration of this fact. The case was one of abscess of cerebrum with choked disk; meningitis basilaris and perineuritis, also neuritis interstitialis optica, but at no time elevation of temperature. We find vertigo, and less frequently vomiting, and seldom convulsions or paralysis. It is a significant fact in connection with cerebral localization, that *the principal seat of abscess of the brain, secondary to ear disease, is in the medullary substance, seldom in the cortex*; which fact may account for the absence of certain nervous phenomena in these cases.

In regard to the clinical phenomena of *thrombosis of*

the *transverse sinus*, the symptoms of a painful oedema over the mastoid of the affected side, to which attention was first directed by Griesinger, is of diagnostic value. Schwartze (*Arch. für Ohrenheilkunde*, vi., p. 219) considers this symptom unreliable, but Wreden confirms the oedematous swelling in the region mentioned as a symptom of phlebitis of the lateral sinus, and the cases reported by Rammell, Kolb, Taylor, Moos, J. Orne Green, and others, support Griesinger's view. However, this symptom is not a constant one.

Phlebitis of the cavernous sinus declares itself by a congestion of the vein which empties into it, the ophthalmic, and its branches. As the result of this congestion there is oedema of the eyelid, conjunctiva, forehead, and nasal mucous membrane, entoptic phenomena, and diminution of sight (Wreden¹). These symptoms may, in the beginning of the disease, exist on one side only, but this will only be for a short time, since the disease soon spreads to the corresponding sinus of the opposite side. Congestive papilla alone would not necessarily furnish us with positive evidence of the *locality* of the obstruction since Sesemann² has shown that the superior and inferior ophthalmic veins do not empty the largest quantity of their blood into the cavernous sinus, but into the facial veins; therefore, when symptoms of obstruction show themselves, viz., oedema of the eyelids, fulness of the frontal veins, and exophthalmus, they are to be explained, not by a simple thrombosis of the sinus cavernosus, but by the presence of thrombi at the same time in the ophthalmic and facial vein.

The internal carotid artery, surrounded by the sympathetic plexus, and the sixth nerve, pass through the cavernous sinus, and the third and fourth nerves and the ophthalmic division of the trigeminus are found on its outer wall. We can, therefore, readily anticipate the local phenomena which would be developed in consequence of pressure of the inflamed sinus upon these nerves.

An inflammation of the *cavernous sinus*, is, in the majority of instances, accompanied by meningitis, and writers have heretofore attributed the phenomena of an affection of the oculo-motorius to meningitis; but Wreden describes two cases of phlebitis of the cavernous sinus (l. c., cases 9 and 10, pp. 95-96), which, notwithstanding the absence of meningitis, showed familiar signs of irritation and paresis in the areas of the oculo-motorius and other cerebral nerves. Symptoms of disease in the region of distribution of the trigeminus, occurring in phlebitis of the cavernous sinus, declare themselves most frequently in irritation and paresis of the ophthalmic branch; the second and third division of this nerve show these symptoms only exceptionally. Irritation of the ophthalmic branch gives rise to one-sided headache, sometimes sharply circumscribed, its greatest intensity being in the *forehead* and over the eyes.

Wreden's cases seem to invalidate Griesinger's (*Arch. d. Heilkunde*, iii., p. 446) declaration that the headache is due not to the affection of the sinus, but to the concomitant meningitis. Fixed, one-sided, circumscribed headache is, consequently, of differential diagnostic value in an affection of the cavernous sinus, because it proves irritation of a single branch of the trigeminus; while *diffuse* pain, spread out over the whole half of the head, speaks more in favor of the coexistence of meningitis of the median cranial fossa, whereby the second branch of the trigeminus (before its passage through the foramen ovale), or even the Gasserian ganglion, is involved.

Phlebitis of the *superior longitudinal sinus* is characterized by repeated and violent hemorrhage from the nose, which Wreden considers very significant when accompanied by epileptiform convulsions. This latter symptom is referred to capillary hemorrhage in the corti-

cal substance of the posterior cerebral lobes, produced by obstruction to the venous circulation of the surface of the brain (Wreden).

Phlebitis of the *superior petrosal sinus*, although producing no very characteristic symptoms, would give rise to great congestion in the labyrinth of the ear, with subjective noises and deafness, which is explained by the fact that the veins of the labyrinth terminate in this sinus.

In phlebitis there is almost always a marked febrile movement, and pyæmic symptoms are the rule in this condition. In Case II., cited above, chills were frequently repeated, and the temperature rose rapidly and with very slight remission. In Wreden's case of phlebitis of the cavernous sinus the initial stage was very short. On the first day the temperature rose and without remission to a morning temperature of 102.2° F., and gained in a few hours the maximum of 103.82° F. Such a sudden rise of temperature to a height of 39°-40° C., and more immediately on the first day. Wreden considers particularly characteristic of the beginning of the fever of an encephalic complication in purulent ear affections. Another valuable point in the differential diagnosis of the initial period of the fever, of encephalic complication, in inflammation of the ear, is that it rarely begins with a chill, even when, as Wreden observed in one case, the temperature was 104.18° F.; whereas in the fever of phlebitis of the cerebral sinuses and meningitis diffusa, usually the reverse is the case.

It is of importance that all cases of ear disease with suspicious but obscure symptoms of a cerebral complication should receive a careful ophthalmoscopic examination, and efforts be made to determine its value as an aid to diagnosis in the disease under consideration, and also to ascertain to what extent it should influence the treatment of the ear affection.

In Case III. (the writer's), the cerebral lesion was on the left side; the left eye was the first to become affected, and the first to recover (in the sense that there was no visible change in the optic disk or fundus oculi) and yet its sight alone was impaired. Mr. Nettleship has recently alluded to two cases (they are not reported in full), in one of which a tumor in the posterior inferior part of the right anterior lobe occasioned severe pain, chiefly on the right side of the face and head, with simultaneous double papillitis, and early extreme defect of sight in the right eye, but no failure of vision in the left eye till a year later. In the other case, the only lesion was softening of the under surface of the left frontal lobe, with atrophy of the left nerve. There was rapid blindness of the left eye without changes, and papillitis of the right without failure of sight. The left disk slowly became atrophied, the right recovered.

From the few accumulated facts it appears that the sight is most affected on the side of the lesion; and that papillitis with other symptoms of brain involvement is valuable corroborative evidence, and we also have some proof in the few cases of recovery, after neuro-retinitis and other signs of brain disease secondary to an ear affection, that the optic disk is, so to speak, a sort of indicator for the condition of the brain. But in the present state of the vexed question of the cause of the papillitis, it cannot be said that it tells us much of the locality of the cerebral lesion. Von Graefe's view of venous stasis and the theory of vaso-motor disturbance, are not supported by post-mortem evidence. Prof. T. Leber has more recently advanced a plausible view that the essential part of the transmission is taken by effusion of fluid into the sheath of the nerve, which did not act by simple mechanical pressure, since its quantity was often small, but by its phlogogenic properties. Leber, therefore, explains the origin of papillo-retinitis in cerebral diseases by assuming that the intra-cranial inflammation produces serous effusion which passes into the optic nerve-sheath, and excites irritating action on the papillæ and neighboring parts of the eye.

THE TREATMENT OF SCIENCE BY THE MILITARY METHOD.

By PROFESSOR ELLIOTT COUES,

LATE OF THE MEDICAL CORPS, U. S. ARMY.

THE above heading looks professional, does it not? As if science were to be treated by some approved method, like any other disease. But that is not exactly what I mean. Science is far more capable of treating a military method as it deserves than is any military method likely to turn physician for the benefit of science. The military method of treating science is the method adopted by dunces the world over in trying to investigate what they do not understand, and cannot be made to comprehend. It commends itself by its simplicity, energy, and efficiency. It consists in taking the man who shows symptoms of being scientific out and hanging him in a red tape halter; if he kicks against being strangled it knocks him in the head with an official club, and says: "What a brave boy am I!" And all the rest of the dunces applaud the lynching. I do not see anything else to recommend the method. I never heard of any one who was cured of his science in this way. It is too heroic treatment—not a reasonable "kill or cure" method. It is all kill and no cure. It is what the literary dunces applied to Keats when they tried to cure him of his poetry. The universal mother took her poor child back to her kindly arms, and kissed away his tears. Tragedy like this is rare indeed—rare as are "these glorious sports of nature," as Huxley styles them, who make such tragedy possible. But the principle—the plan and method of treatment—is always one and the same, here, there, and everywhere; it is to-day, was yesterday, will be to-morrow, in civil as in military orders, applied alike to science, art, and letters. Applied to quivering flesh and shuddering spirit by that thing which has neither body to kick nor soul to damn—I mean the Confederacy of Dunces. It is simple, energetic, and effective, as I have said; but this kind of heroic treatment is open to serious objection. For it is the heroism of the Dunce. And what a brave boy he is, to be sure!

I cannot imagine how the preceding paragraph ran off my pen. I did not mean to speak of dunces—I never knew one who was not abundantly able to speak for himself, and the sound of his voice is familiar, if not musical. My idea was to say something about the relations between scientific and military affairs; about the position which I think the Army and Navy ought to take regarding scientists who are in military service; and especially about that curiosity known in the medical corps of the Army and Navy as a "second examination," or "examination for promotion." What I have to say is mainly prompted by Captain R. W. Shufeldt's article, entitled "The United States Medical Service," in a recent number of *THE RECORD*. I hope Dr. Shufeldt will follow up the subject. I like his way of putting it. He has a good sound case, and his vein will bear working. Granted, with Professor Huxley, that examination, thorough and searching, is an indispensable accompaniment of teaching, it does not follow that examination which has nothing to do with teaching is indispensable. In the latter case, it seems to me not even a necessary evil, but simply a nuisance, and no nuisance can ever be necessary. This second examination in the Army or Navy, of course, does not profess to *teach* anything. Does it learn anything, or discover anything? If an officer "skins through" by hook and by crook, is he not just as well off as one who sails through by luck, pluck, and force of circumstances? His position in the Army is not affected appreciably. He goes back to duty, and nothing has been lost or gained. If he is plucked, he goes back just the same, and makes it his duty to cram and come up again. He crams, comes up, passes, and knows no more or less than he did before, and is no better or worse doctor. To cram knowledge is not to know; crammed knowledge is invariably disgorged as

soon as the crisis is over, not digested and assimilated, and made a living power, as all real knowledge is. The man's consuming power, not his productive power; his capacity for containing, not for retaining; his mental endurance, not his mental armament—these are what have been tested. And this is the very test that some of the best men should not be obliged to endure, for they are the very ones least fitted to undergo such an ordeal. The man of mediocrity stands a better chance than they do, and generally passes a better examination.

The thing doesn't hurt the one as it hurts the other; and there are men—few, it is true, but there are men—whom to hurt seriously is to kill; whom to wound in spirit is to destroy. And *that* man is just the one who is worth the rest of the regiment. He is the one who lacks the heroism of the dunce. He is the one who demonstrates the military method of treatment, where scientific treatment should have been given instead, by turning the drama of examination into a tragedy. The possibility of such a grave contingency as this is enough to condemn the whole system.

The second examination has its merits, as "a sieve to catch the bad rats." I am satisfied that this is its principal merit, and its only recommendation. This raises the question, however, whether rat-catching is a dignified or desirable occupation for any army officer, under whatever name and style it may be pursued. To call it and treat it as a medical examination strikes me as the military method in full bloom—one of the most military methods that could be devised. The military method is the method of brute force, in its most brutal and forcible exhibition. It is applicable to insurrections, and rebellions, and revolutions of nations, but it does not apply to rat-catching. Nobody ever caught a rat by brute force—not even a rat-terrier could do that. He is instinctively strategic; and his instinctive strategy is simply the scientific treatment of the case. The military method is in order after the rat is caught—not before. A rat, and especially a bad rat, is apt to be an old gray rat, whose science is quite equal to any test that can be devised by an examining board. In this case it is ten to one on the bad rat, as against the man I described in the last paragraph.

Since the examination proves futile in the rat's case, and dubious or even dangerous in the man's case, let us see if it is not also entirely superfluous in any case. The military idea is, that the examination determines an officer's fitness for the position he holds, and for promotion to a higher position in due course. But that is absurd. It does nothing of the sort. It simply demonstrates an officer's fitness to pass an examination—absolutely nothing more. His fitness for his position, or his unfitness, is perfectly well known before. He has been in the service at least five years, perhaps ten or fifteen. He has been busy telling people whether or not he is fit for his position every day of his life during that period. He has built and furnished his house, for better or worse, and hundreds of his brother officers know it perfectly well when they see it. So do a thousand soldiers. In short, he has made his reputation, whatever it is. It is all abroad; it is in the air—pshaw! there is not a clerk in the surgeon-general's office but knows well enough how that officer "stands." Individually, of course, no clerk, no soldier, no line-officer, is as good a judge of the man's fitness for the position as any one of his medical examiners. Collectively, however, judgments of the rank and file is absolutely conclusive; nothing that he can say to his examiners, nothing that he fails to tell them, nothing that they can tell the surgeon-general, alters the case one iota. How should it, indeed? How should a conversation held for an hour or two with his examiners, when he is probably under strain and stress of mind, and of all hours in his career the least likely to appear himself, bear upon that silent, stealthy, steady inquisition he has endured for years? The latter is the examination that tells the true story; if his thousand and

one examiners consider him fit, he *is* fit, and there is the end of it—or ought to be. And if, after all that, the Board says he is unfit, why, the Board is doubtless mistaken—that is all.

Depend upon it no Board is going to find out anything about a candidate that everybody did not know before, excepting his ability to pass an examination under every possible disadvantage. If the Board differs with public opinion, the result may be mischievous, even dangerous; if it agrees with public opinion, it is at best an elegant superfluity.

I will go one step further, and say, that almost any officer of the medical corps is a better judge of his own proficiencies and deficiencies than any Board can expect to become under the present system of examination. He knows himself a great deal better than they can find him out, and could give a stricter, sounder, and more reliable account of himself under almost any other method of being called to account than the one now in vogue. And an officer of the medical corps of the army is almost invariably a man who would *do it*, too, fairly and squarely, saying just where he felt weak and where strong, just what opportunities he had had, and just how he had improved them, and just what he needed, moreover, to enable him to reflect the most credit upon himself and his corps, and do his patients the most good—all of which he is scared out of doing the moment the examination-battery opens fire on him.

I think, therefore, that this examination business is in the first place dangerous, in the second dubious, thirdly futile, fourth superfluous—in fine, a military method of treating science, when what it ought to be is a scientific method of treating a specific military contingency. That it is occasionally amusing, however, I can easily show.

Some ten years ago, holding then substantially the same theories upon the subject that I have here voiced, I was ordered before the Board. I had been nine or ten years in the service, mostly spent, as usual, in the West and South. I had some reputation, such as it was, as a scientist; none at all in the profession of medicine, for which I never had any fancy or any ambition, and in which, consequently, I never displayed any special aptitude or excellence. I had doctored people to the best of my ability, cut off their legs and arms occasionally, taken care of government property, sent in regular reports, and obeyed orders—always in an automatic and perfunctory way, with my head full of other things in which I took a vivid, resistless, and irrepressible interest. I was at the time writing some books at the Smithsonian in Washington, and expected to continue to do so indefinitely—and, in fact, I have done so ever since. The order came without warning—though if I had been told to expect it every day for five years before, it would not have made any difference, I suppose. I voted the whole thing a bore; and being very busy indeed, wanted to get rid of it as soon as possible. I could not possibly have spared the time to do any cramming, had I been given opportunity to do so, and should never have been better prepared than I was at the moment. I did not expect to be thrown, I confess, but I knew perfectly well the Board could do so if they wished to; so I reasoned that I had better make it as pleasant as possible for the gentlemen I was to meet by not troubling them to put too many questions, the replies to which might not affect them agreeably. In fine, I was disposed to waive answers altogether, and so leave the Board quite free to act at its own discretion. I went to New York immediately, and had a good time for a few days with some officers who were there on the same errand, and then presented myself. After passing the compliments, and having some pleasant chat, “the trouble began.” One of the gentlemen asked me about rheumatism and Bright’s disease. I said that I did not know whether the blood was acid or alkaline in the former disease, nor how to cure it; and that I had never seen a case of Bright’s disease. Another asked me what I

thought of somebody’s theory of phthisis. As I had never heard of the theory or its author, I said very truly that I did not think much of it, but presumed it had its merits. Another asked me about some delicate operation upon the eye, and I said I had never operated upon the eye, and never expected to. Things began to look queer, and it was odd-or-even whether I could make my theory of examinations work in that particular instance. But when it came the President’s turn to interrogate me I felt easier; for I knew by common report that he was going to ask me what an aspirator was, and I had taken the trouble, that very morning, to hunt up one and master its mysteries. The contrast between my bold and cheery reply to this momentous question, and my previous remarks on other topics, was too much for the gravity of my examiners, and there were five gentlemen grinning at one another like Cheshire cats in a moment. The aspirator finished the interview; and taking a hint from the President, with alacrity I bowed and withdrew. A few days afterward I received a letter from the Surgeon-General, informing me that the Board had found me qualified for promotion, but that I had apparently not kept up with the progress of medicine. Why, bless my soul, I could have told General Burns that, if he had asked me, instead of sending me to New York to prove it to four army surgeons by hunting up an aspirator! What puzzled me was, how did they discover that I was qualified for promotion? Excepting the aspirator, I had not given the slightest sign of knowing anything about my profession, to say nothing of keeping up with it. But I reflected that that was the Board’s business to discover, and how they did it was a conundrum I was not obliged to answer. Remembering, also, that I could catch up with the procession at any time I wanted to, I lighted a cigarette with the Surgeon-General’s communication, and thought no more about it.

But now, what were the actual facts in this case? How came the Board to make a favorable report on such an unfavorable basis? I take it, simply this: the report was not based upon anything that transpired in the examination-room, except in so far as a friendly rap over my official knuckles was given, to save the Board’s official conscience. If I had passed even a tolerable examination, the report would have been the same, minus the rap. I had simply presented myself *in propria persona*, and the report was wisely, justly, and courteously based upon what I was, not on what I happened to say or not say in that brief hour. My theory was proven: the examination was a nullity in my case, *and properly so*. Why? Because my examiners did *not* apply the military method to the treatment of science, having discrimination enough to apply the correct, which is the same as the scientific, method to the treatment of a military contingency. It was, in short, a piece of dunce-business we were about, they and I; and we both got out of it by rising superior to it.

Some one may rise to object, at this point, to my ungracious way of remarking upon what was, according to my own showing, great forbearance on the part of my examiners, and great good luck for me. I think I recognize the sound of the objector’s voice. It is a familiar one, not a musical one. No “forbearance” was shown me; the case did not require, nor indeed admit it; it was simply decided on its merits.

Take another case. I was recently conversing with a medical officer who had been thrown. It pained me to see the effect it had upon the man. Not that it hurt him in anybody’s estimation but his own, or is likely ever to do him any ostensible injury—nobody cares a straw about such things but the man himself. Nor did he—or could he—complain that the examination was not fair and just, or that he had not failed fairly and justly. So much the worse! It was a refined piece of wanton cruelty to which he had been subjected, leaving him not even the vantage-ground of complaint whereupon to settle the affair between his wounded spirit and him-

self by abusing his examiners, and proving himself an injured man. I knew this gentleman intimately, having served with him, and in fact been his patient more than once. His reputation, if not a brilliant one—as it would become should opportunity offer—was enviable. He was liked and respected by his associates; he enjoyed the confidence and respect of his patients; was zealous and faithful in the discharge of his medical and military duties; kept a good hospital; kept his accounts straight. He was sound, mentally and morally; not very strong physically; scrupulously nice, even over-sensitive, on a professional or personal point. Very well: he is ordered before an examining Board to plead a case of self-defence, counsel and client in one; a case upon which grave consequences appear to him to depend. He proves unequal to that emergency, and is advised that he may try it on again pretty soon, and must make it go next time, or go himself. Six or eight years of examination creditably sustained at the hands of a thousand self-appointed inquisitors go for nothing.

This officer, I contend, has been both wronged and injured. He has been wronged, by being subjected to needless cruelty, issuing from a cast-iron system, too hard and military to be applicable to the requirements of his case. He has been injured, too—injured mentally and physically—stung to the quick, wounded where he lives, in his very marrow. Without regard to the humanities, viewing him simply as a physiological mechanism, he has been put to a wrong purpose, and in handicapping him in this way, the service is crippled to the extent to which this particular cog in the wheel has been bruised and bent. All the boring and cramming he can do will be no offset to the deterioration the machine has suffered in being set to do a needless piece of work—"pass an examination." If I, or any other officer who had served with this one, and knew him well enough to give an intelligent and reliable account of him, had been asked to testify, we should unquestionably have done him that justice which, it seems, he was unable to do himself. This was probably a case the reverse of my own; one which—through no fault of the examiners—hinged upon a pernicious system, based upon a radical dunce-theory. It were far better, I think, to satirize the theory, and kick the system out of court, as I did, when I was satisfied that it would never do to let it be applied to me.

Since Dr. Shufeldt has adduced his own case with an audacious candor and confidence I cannot sufficiently admire—enough to send the cold-creeps down the spine of any well-regulated military man—I feel free to speak of it also. Now that he is out of the woods he can afford to laugh; but I suspect that the worst use he could have been put to, next to hanging, was that which he was put to when he was sent before the board. In the first place, needless pain was inflicted—always a stupid and unscientific thing to do. Secondly, he spent a year in grubbing a lot of old text-book bricks out of the cellar of his mind's house, and polishing them off for his examiners' inspection. That was so much time wasted, to say nothing of the mental friction required to think clearly with a load of useless bricks in the upper story. No mind works well when encumbered with unnecessary facts. Library shelves were made for a purpose; and, as old King George III. used to say, the greatest lawyers know no more law than the rest—only they know where to find the law. I cannot suppose that Dr. Shufeldt is any better officer or any better doctor for having succeeded in an examination, any more than I supposed him the contrary when he did not succeed. Nothing is proven either way, excepting the ability to work under stimulus, as Huxley says.

Knowing Shufeldt as intimately as I do—and I have for some years watched his career with special interest—I should say he was the last man who needed stimulus to work. He is whip and spur enough to himself; one upon whom the lash of the military method should never be suffered to fall; for when it does fall, as it did at his

first examination, the service suffers specifically to the extent to which he is injured himself. The medical corps loses exactly what it costs Dr. Shufeldt to catch up with his examiners and get himself in working order again; for all the effective energy he spent in that affair was simply wasted, and the corps gains nothing in return. To pass or not pass an examination is nothing *per se*.

What Shufeldt needs is neither stimulus nor discipline. He needs an opportunity, not an examination, in order to be put to the best use the army can make of him. So long as any man is voluntarily a member of an organization, civil or military, certain regulations and restrictions must be enforced in his case; but the greatest good to the greatest number is likely to come when rules are best adapted to the individual. It is the military method again, instead of the scientific, when all rules bind alike on all persons. The wisest discipline leaves the widest margin for individual idiosyncrasies; the right solution of the personal equation solves the general problem. To make a square peg fit a round hole is as impossible as the quadrature of the circle. One of two things must happen. Either the peg wears round, and sinks into the hole at last, or it stays square, works loose, and is gone. Nothing but friction during either process.

If I am not greatly mistaken, Dr. Shufeldt was cut out for a scientist, and has the requisite qualifications to become a great naturalist. I think I recognize the spark that is in him. If it is there, and no mistake, nothing can extinguish it, and I thank God every day of my life that there are men in the world whose inner light, like Greek fire, can burn under water, if needs must be. The practical question is, not whether such fire can be put out, for that is impossible, but what is to be done with it? Is it to be a producer or a consumer? Either is possible, equally possible, I almost said. Let it produce, and the world is the wiser and richer; for ideas are born in that kind of fire, and ideas are imperishable, and rule the world absolutely. Let it consume—well, ask Keats, for example, *what* it consumes.

On my theory that this young naturalist has the spark, he does not belong to the army. On the contrary, the army belongs to him, and nothing that the army can give him is too good for him. He never ought to know a "commanding officer." He never ought to hear sick-call blow. He never ought to see a patient. He never ought to put on a cocked-hat, and strap a sword on—that is, if my theory is correct. Give him only the necessary conditions of environment, and prove me wrong if am wrong. If I know anything, I know a naturalist, and I know what a naturalist needs—what a naturalist must have—what a naturalist will have, in or out of the army.

But, you say, this Dr. Shufeldt, is he not an army surgeon, paid by the Government to perform medical duty? Why should an exception be made in his case? He is not hired to be a scientist, he is hired for a doctor. What business has he to be writing books instead of attending to the sick and wounded of the army? What is all this long, rambling tirade about sparks? What is this man driving at anyhow?

My dear sir, I will tell you what I am driving at. I am driving at you. I do not recognize your face, but the sound of your voice is familiar and unmusical. I see that you have a red-tape halter in one hand, and an official club in the other. I see that you are a brave boy, but you belong to the Great Confederacy. You have the heroism of the dunce. You are the "Treatment of Science by the Military Method."

SMITHSONIAN INSTITUTION, WASHINGTON,
September 1, 1883.

TO REMOVE WATER FROM ALCOHOL.—If gelatine be suspended in ordinary alcohol it will absorb the water; but as it is insoluble in alcohol that substance will remain behind, and thus nearly absolute alcohol may be obtained without distillation.

MANGANESE AS A STIMULANT OF THE MENSTRUAL ORGANS AND AS A REMEDY IN CERTAIN FORMS OF AMENORRHOEA AND MENORRHAGIA OR METRORRHAGIA.

By FRANKLIN H. MARTIN, M.D.,

CHICAGO, ILL.

SINCE Ringer and Mussell, of London, called the attention of the profession to the gratifying results obtained in experiments performed by them (*Lancet*, January 6, 1883) in the treatment of certain forms of amenorrhœa by permanganate of potash, I have taken advantage of every opportunity that has been afforded me, both in dispensary and private practice, to satisfy myself as to the action and efficacy of the new remedy in that direction. I have been more than gratified with the result. I have found that manganese will not only relieve certain forms of amenorrhœa, but also of menorrhagia and metrorrhagia. It is, of course, unnecessary to say manganese, or any other one remedy, cannot be expected to relieve all cases of amenorrhœa or menorrhagia, when each is dependent upon so many different causes. As amenorrhœa is only a symptom, not a disease, it would have been much more satisfactory if Ringer and Mussell, in their little article, had mentioned with greater explicitness the peculiar forms of amenorrhœa in which they found their remedy to exert its great influence.

From my observations I have been led to consider manganese in any form a direct stimulant to the uterus and its appendages. It may exert this influence by acting as a direct vasomotor nerve-stimulant to the vascular system of the parts, and in consequence of the improved circulation directly increase the tone and nutrition of the organs, or it may exert its whole force through stimulation of the sexual nerve-ganglia, or even possibly the sexual *nerve-centres*, thereby bringing the organs to their normal state of action. At any rate, its action is prompt and direct. In bringing the uterus and appendages to a normal state of menstrual tonicity, when the lack of tone is dependent upon some previous depression of innervation, manganese, in my opinion, certainly has no equal. Even when the cause of the depressed innervation is still acting, this remedy will exert its stimulating power over the menstrual mechanism. In consequence of phthisis, menstruation had not occurred in a young woman, eighteen years of age, for four months. Experimentally the manganese was given in connection with her other treatment. Menstruation occurred within a week. Another young woman, twenty-four years of age, with an aggravating digestive trouble of some years' standing, had become very irregular—flowing profusely for a week or two, then scantily for an equally irregular time, again followed, perhaps without any warning, by a profuse flow or as likely a complete cessation. This state of affairs had been going on for more than a year. There was no pain with the flow. She was very weak and anæmic from the effects of indigestion and loss of blood. This patient was given two grains of the permanganate of potash, dissolved in one-half glass of hot water every night on retiring. It was kindly received in this way by the irritable digestive organs. In a very short time there was a decided improvement in the menstrual trouble, and the patient has since menstruated three times normally.

In young girls who are irregular in the early months of menstrual life, where it is simply caused by the natural weakness of the partially developed organs of generation, or where, from an overworked nervous system, the organs are robbed of their natural nerve force, this remedy seems to possess the stimulating properties requisite to bring them into healthy action. A remarkable case of this kind was that of a young girl who had menstruated once. Eight months had passed, and the menstrual flow had failed to appear again. The mother of the girl, being alarmed, sought advice. The permanganate was given in two-grain doses twice a day. Within a week the girl menstruated the second time in her life. In two other

cases of "missing" in young girls, without any apparent cause, or any other symptoms, the remedy given in the same doses a few days before the next regular period was expected, stimulated the organs to a normal flow. The action of the manganese was so prompt in these cases that I am convinced it was no mere coincidence.

It is well known that from exposure to cold the weakest organs of the body are the ones most liable to suffer. A woman, who, when exposed to cold, immediately suffers suppression, cessation, or excess of the menstrual flow, will invariably be found to possess susceptible and weak menstrual organs. In cases of this kind, viz., suppression, cessation, or excess of the menstrual flow, caused by "catching cold," with no other apparent cause, the most gratifying and prompt results are obtained from manganese. The above variety of cases are of so frequent occurrence that in them I have had numerous opportunities to test the new remedy, and I have yet to see it fail, in either amenorrhœa or menorrhagia, when due to the irritation of cold alone. In several cases where the flow was a week or ten days overdue, from "catching cold," the permanganate was given in large doses, and its almost magical effect demonstrated by the flow appearing within twelve hours.

Although I have had greater opportunities for testing the value of manganese in amenorrhœa than in menorrhagia or metrorrhagia, I have received unmistakable evidence of its power in the latter forms of menstrual trouble.

Menorrhagia and amenorrhœa in their outer manifestations are exactly opposite in nature, but they are very often dependent upon the same causes. When the cause is anæmia, or any depressing constitutional disease producing a perversion of the functional activity of the menstrual organs, and this perverted action consists of an irregular or excessive flow, this condition will as readily succumb to the stimulating effect of manganese as when the opposite condition exists. The following cases are of interest: A woman, aged twenty-six, sought advice for excessive and irregular flowing. She had been married two years and had one child, twelve months old. The child was large and strong, the mother physically slight. The mother nursed the child. For ten months she had stood the strain very well, when she commenced to fail, suddenly grew weak and anæmic, and began to flow excessively. This continued with but a few short irregular remissions until I saw her at the dispensary. She was given two-grain doses of the permanganate of potash four times a day, at the same time all other treatment was withheld. In three days the patient returned saying that the flow had stopped the next day after receiving her medicine. I then discontinued the manganese, prescribed iron and nourishing food, and she continued to improve. By digital examination nothing abnormal was found in the above case. Another case was that of a large, stout woman, thirty-five years of age, who came to the dispensary suffering from menorrhagia. Her menstrual periods were regular as to time but the quantity of blood was alarmingly excessive and would last for two weeks. She was married, had three children, the youngest three years of age. This abnormal condition of menstruation had been coming on by degrees for a year. The uterus was a little enlarged, and soft to the touch, otherwise, by physical examination, nothing abnormal. Four days before the expected flow she commenced taking the permanganate in two-grain doses three times a day. Menstruation came on at the expected time, and after a normally free flow for four days passed off naturally. Before the next period the same treatment was repeated, with the same marvellous result.

I have been particular to give here only typical cases. In a number of other cases I have received very gratifying results, and I am myself convinced that in properly selected cases others will be able to obtain like results.

Although manganese, like the allied metals, nickel, zinc, iron, and silver, has a direct influence on the blood as a tonic in anæmia, chlorosis, etc., it cannot be pos-

sible, in my opinion, that its peculiar influence on the catamenia can alone depend upon that virtue. To influence the organs of menstruation by acting as a general tonic, would necessarily be a slow process, and the effect would be very gradual. It undoubtedly, however, as a general tonic, has a predilection for these organs. This was noticed and commented upon by W. H. Broadbent, of London, after experiments performed by him, and recorded in the "Proceedings" of the Clinical Society of London for 1868-69, vol. ii., p. 122: "Manganese," he says, "seemed to have a special influence in promoting the return of the catamenia, and nickel a special property of checking leucorrhœa." But one can readily see by the character of the cases reported by Ringer and Mussell, and myself, that manganese must have a more direct mode of influencing the menstrual organs than by the necessarily slow one of a general tonic. As to what that influence is, I am not prepared to advance any more definite opinions than have already been included in this short article. I shall look with great interest in the future for the results of other experimenters in this direction, while personally taking advantage of every opportunity presented to extend my knowledge on the subject.

In prescribing the permanganate of potash (the most convenient preparation in which to administer manganese), it will be well to bear in mind a few points of importance. The preparation has a disagreeable, distressing effect on the stomach when taken undiluted, which may be obviated by administering when the stomach is full—immediately after eating—or dissolved in considerable water. In administering the permanganate in pill form, it must be remembered that excipients ordinarily used by dispensers will produce with the drug spontaneous combustion. The following basis has been found to act well: "Vaseline two parts, paraffin wax one part; melt, stir till cold, and add kaolin, three parts; mix well," roll out, and dust with kaolin (*Lancet*, January 13, 1883). Dry gelatin capsules I have found to be the most convenient form in which to administer the remedy.

THE BROMIDE OF SODIUM IN THE TREATMENT OF EPILEPSY.

By J. LEONARD CORNING, M.D.,

NEW YORK.

IN a recent lecture by Professor Dujardin-Beaumetz, published in *THE MEDICAL RECORD* of August 25, 1883, the following sufficiently remarkable statement occurs: "I have made many trials of bromide of sodium in epilepsy, and notwithstanding the considerable doses exhibited—ten to twelve grammes a day—I have never succeeded in arresting attacks either of petit-mal or grand-mal by this salt. I have therefore been astonished to see in Hammond's remarkable work on 'Nervous Diseases' that this eminent neuropathologist gives the preference to bromide of sodium in epilepsy." To American practitioners, at least, the above statement cannot fail to excite astonishment; not that it is at all extraordinary that there should exist some difference of opinion respecting the relative therapeutic value of the various bromides, but rather because the particular preparation known as the bromide of sodium should have been singled out as an object of disparagement. Now, if there is one fact relative to the bromide more thoroughly established than another, it is the superiority of the sodium salt, and for this reason, that the prejudicial effects which are so conspicuous a concomitant of the other bromide preparations are in great part absent in this (the sodium) salt. In this connection Dr. W. J. Morton says (*vide* Dr. Morton's admirable paper on the "Treatment of Migraine," *Medical Gazette* for July 21, 1883): "It is a matter of clinical experience that larger doses of bromide of sodium may be tolerated for months without evidences of the bromide rash and without failure of the health."

"On the contrary, a patient thus treated gains flesh, eats well, and has good color." "For instance, M. B—, treated for epilepsy, has taken 90 grains of bromide of sodium daily for one year and is the picture of health."

This is a *multum in parvo* of the whole question. We give the bromide of sodium, not because we expect to prevent the attack with more certainty than with the potassium salt, but because we hope to avoid the inevitable disadvantages to general health which are the result of a considerable and prolonged employment of the latter preparation.

But Dr. Dujardin-Beaumetz tells us that he has not succeeded in arresting the attack with the sodium salt. Now if there is one fact more thoroughly established than another, it is the ability of the sodium salt to arrest the epileptic seizure, not alone for weeks and months, but even for years. Thus my friend, Dr. M. Josiah Roberts, of this city, has recently communicated to me the history of a case in which he succeeded in reducing the number of attacks from two or three a week to only one every three or four months for three years, by the use of the sodium salt; and doubtless the result might have been materially improved had the patient paid due heed to general prophylactic measures.

I have employed the sodium both in epilepsy of adults, as well as in that of young children, exhibiting the remedy in far larger doses than could have been possible had the potassium salt been employed, and not only was the attack satisfactorily arrested but the general health of the patient showed substantial improvement, as proven by a considerable gain in weight. This was particularly true of a boy of fifteen years, who before treatment often had as many as four attacks in a single day. When I first saw this patient he was suffering from the bromide rash and his mental condition bordered on dementia, he had been treated with heroic doses of the potassium salt. Appetite was poor and general appearance of patient emaciated in the extreme. Owing to the sickly appearance of the boy his family had discontinued the use of all medicine, and the fits had returned with all their former severity. I ordered the bromide of sodium in forty-grain doses three times a day, and put the patient on eggs and milk. At the end of three months there had been an actual gain in weight of nearly twenty-five pounds, and the number of fits had been reduced from an average of about three a day to two or three a month. So great was the change in the mental and bodily condition of this boy that his own mother who had been separated from him during treatment hardly recognized him. Besides the above case, which is sufficiently striking, as exhibiting the remarkable constitutional effects of the remedy, I can recall several other instances in which I have had occasion to witness the wonderful effects of the bromide of sodium in epilepsy. As a matter of course some sort of attention should be paid to dietetics and general hygienic rules; but the same may be said with respect to almost any other remedy which has been employed in epilepsy. There is, therefore, no doubt that in bringing the bromide of sodium prominently before the profession in connection with the treatment of epilepsy, Dr. Hammond merits the gratitude of all who are interested in the therapeutics of this most frightful disorder.

As to the lack of success attending Professor Dujardin-Beaumetz's attempts with the bromide of sodium, I can only find in them one of those unaccountable exceptions, which, if not refuted promptly, is calculated to mislead those whose experience with the remedy in question is as yet limited. This seems to me the most charitable view to take of the case. To those, however, who have become intimately acquainted with the manifold advantages of this wonderful remedy, not only in epilepsy but in very many other neuroses, it must of necessity cause no little astonishment that a gentleman of such prominence as Dr. Dujardin-Beaumetz deservedly is, should at this late day, question the efficacy of such a well-established remedy as the bromide of sodium.

SOME REMARKS ON CANCER.

By JOHN FERGUSON, B.A., M.B., L.R.C.P.,

ASSISTANT DEMONSTRATOR OF ANATOMY TORONTO SCHOOL OF MEDICINE.

THOROUGHLY convinced that carcinoma is a local disease, and arises *de novo* as the result of some form of injury or irritation to the part that becomes affected, I began a series of researches in the year 1878. The result of these investigations I shall now briefly detail.

It is quite needless to say that cancer is of the epithelial type. There is nothing abnormal in the fact of its being epithelial, but in the fact that the epithelium occurs where it should not, and is arranged after a manner differing from that of normal tissue. There is evidently a date previous to which a tumor that ultimately becomes cancerous is not cancerous, in other words that there is a pre-cancerous period to such new formations. When and where to draw the exact boundary line between the condition that is yet benign, and that malignant, devouring state called a cancer, is not easily defined. Another question of great difficulty, yet of great importance, is, why the same kind and extent of injury, as far as we can judge, acts as the initiative which produces this dread disease in one person while it fails to do so in another.

The answer to this question I think we are to seek in what I shall call a constitutional tendency. I am strongly of opinion that this tendency in different diseases has not received due attention. A child is born free from any disease, yet with an inherited tendency to some form of ailment in one or other of its tissues. If this tendency to take on diseased action be marked in the case of the secreting glands, and particularly if this tendency exist in the epithelial elements, we have the main conditions necessary for the production of a cancer. There may be several existing tendencies in the epithelial cells of the skin and glands; still, as regards the genesis of cancer, I think the rapid multiplication of the cells is the most potent factor.

One fact to which I have paid much attention is that a cancer is not infective until the definite structure of this new formation has been evolved. Thus, so long as the secreting tubes of the affected gland are packed with epithelium, but no epithelium can be detected in the tissue outside of the tubes, while no alveoli are found filled with these cells, there is no infecting power to neighboring parts and adjacent glands. I make this remark very advisedly. While the secreting tubes are thus blocked up and filled with epithelium, but none found in the gland tissue, we have what may be regarded as the strictly local stage of the cancer growth. Once, however, the disease has advanced so far that the epithelial cells can be discerned in groups throughout the gland, there is no further safety from infection.

Another point of great moment is from what element in the gland does the cancer take its origin. To this I answer unhesitatingly, the epithelium. If we take a cancerous breast, which the surgeon has removed, keeping well clear of the diseased tissue, with the idea of preventing its return, then, after carefully preparing a great many sections of the tumor, we shall find that a section taken from the truly cancerous part will reveal all the histological characters of the disease; a section nearer the edge of the tumor often shows these conditions in a less marked degree; a section still farther out shows them still less definitely; and so on gradually, till all that can be detected as wrong is simply the secretory tubes crowded with epithelium. Follow in this manner, taking section after section, gradually proceeding to the outer parts of the tumor, and finally we reach healthy tissue. Should the removal be complete, and no neighboring portion of the body have become affected previous to the extirpation of the diseased mass, freedom from a return will likely have been secured. During the past five years I have examined twenty-three cancerous mammae, and with-

out exception found the above law to hold good. What does this argue? It seems to me that the only conclusion we can draw from this is that the diseased process begins in those tracks and channels that are lined by epithelium; and from these, as starting-points, invades the connective tissue of the gland.

The following case came under my notice: A young woman was delivered of an illegitimate child in December, 1882. About three weeks after she had an abscess in the left breast from exposure to cold. This I opened freely and it soon healed. In June she came to me, saying that she could not sleep for the pain of this breast. The pain steadily grew more intense, and I advised her to have it removed. Going out of the city for a short time for her holidays, she died of some acute abdominal trouble. I succeeded in getting the diseased breast for examination, and shall state briefly what I found. Nearly three hundred sections were examined. Throughout the entire gland the ducts were full of proliferated epithelium, while only in one small portion could the true appearance of cancer be found. This was about one inch from the point where the abscess had been incised. This was the most advanced part of the disease, and it was here only that the epithelium could be found in the inter- and peri-glandular connective tissue. Had this woman died a little sooner, no cancer tissue would have been found; had she lived a little longer there is every reason to think that the whole gland would have been more or less infiltrated.

Another point of great moment is the infectiousness of cancer. Although, as I have shown, cancer arises from some injury done to a part by which its normal elements are deflected into an abnormal arrangement of themselves, still after a time it loses its purely local nature and steps out into neighboring parts. It has long been observed that cancer affects the lymphatic glands lying near it, and on that side toward which absorbed material passes. In what way the glands become infected is a question that lies at the bottom of a long series of important facts, both pathological and therapeutic. Lymphatic glands above the seat of some irritation often become enlarged. As an example we might mention that of a boy who bruises his foot, and as a consequence of this the chain of glands in the femoral and inguinal regions become enlarged and painful. But as soon as the source of trouble in the foot is removed, and a little rest obtained, the tender and swollen glands become normal. It is not so in cancer. Once the glands have begun to enlarge, say in the axilla, the removal of the diseased mamma will not suffice. In this case a set of pathological changes are started which do not spontaneously stop. This points to the fact that it is not a simple irritation of the glands. The truth is that the same kind of changes are established in the gland that previously existed in the breast. Take one of these axillary glands and subject it to a most thorough microscopic examination and we find what we found in the cancerous breast. The secreting tubes are crammed with proliferating epithelium, presenting the same appearance as to size and arrangement of nuclei which was noticed in the parent source of infection. In more advanced stages of the disease in other sections of the same gland, or in sections of other glands, these epithelial cells can be detected passing beyond their proper limits and invading the walls of the secreting tubes; still further advanced, they can be found outside of the tubes in the gland tissue, and a little more and the alveolar arrangement of the cells and inter-glandular connective tissue is seen. Here is a set of events by which a new formation, or sort of new existence, is established within the animal body. By sowing apple-seeds varieties of apples are obtained; but by grafting, these varieties are perpetuated. A sort of species of tissue arrangement was originated in the breast as the result of the injury inflicted upon it; or, as the consequence of long-continued irritation. Once this kind of tissue species is

formed in the mammary gland it is conveyed to the near lymphatic glands, on the principle of grafting; when tissues have run into the carcinomatous mould there is a very strong tendency to reproduce themselves; and it matters little where they may be planted, if they take root at all, it is only to develop a cancer.

From the examination of nineteen very suspicious cancerous breasts, it does not appear that there is much tendency, if any, to affect the lymphatic glands, until that stage of new life is reached when the epithelium is distinctly abnormally situated. It is not until these cells are found without the secreting ducts and grouped in the connective tissue that we find any power to cause infection of the glands above. The nineteen cases just mentioned were in the very earliest stages of diseased action when the ducts were packed, but no alveoli formed. The appearance, however, so far as it went, was such as invariably occurs in the growth of a typical cancer. Most of these specimens were obtained from cases where death had taken place from some other affection; a few only where the mamma had been removed on the ground of suspicion. The great probability, indeed certainty, is that these breasts were cancerous in the early stage, judging both from clinical and microscopic characters obtaining in each. The only part in the evidence wanting to confirm their cancerous nature was the absence of definite aveoli containing groups of cells.

In another group of cases in which there was enlargement of the axillary glands, a microscopic examination of the new formation in the breast always revealed the true characteristics of cancer. This showed that in order to infect the glands the disease in the breast must have advanced to that stage, at least, when the epithelium is found in the connective tissue outside of the walls of the ducts, in a locality where it should not exist, and is abnormally arranged.

There is some peculiarity about cancerous epithelium which we may never be able to fully determine. It has a tendency all its own, so that when it is planted in a structure, as yet healthy, it has the power of producing diseased action, and this I think in two ways: First, by the proliferation of the diseased cells carried from the affected to the non-affected parts; and secondly, by exciting a diseased action in the epithelium of the part to which the infecting material is carried. This is what we might call the intrinsic quality of the epithelium from a cancerous gland. According to some of our great pathologists, there is no such thing as a cancer cell; according to others there is a difference in the so-called cancerous epithelium and that which is healthy. By these latter the epithelium is regarded as larger, more varied in form, and with larger and more distinct nuclei and nucleoli. The results of all my own observations, taking the great average of cells, is in favor of the latter view. Setting aside all microscopic distinctions, however, there is some vital property which, existing in certain epithelial cells, pre-eminently entitles them to be called cancer cells. We cannot under the microscope tell what spermatozoön would be capable of transmitting syphilis, and yet such a power may be resident within it.

At what period of the life of a new formation, destined to become cancerous, the elements of which it is composed acquire infecting power, we do not at present know. A few experiments may help to settle this question. A breast was removed in which the cancer condition was well marked. As stated at the beginning of this article, different sections gave different results. In some the ducts only were so crowded with epithelium, in some these cells existed outside of the duct-walls, and in some the alveoli and cell-groups were found. From that part of the diseased breast which yielded a good sample of cancer tissue I placed a number of grafts in the parotid and submaxillary glands of three young dogs, and awaited the results. The dogs grew, and in two out of the three cancer developed in the glands so treated. From the same breast, but from parts that did not yield

the cancerous arrangement of tissue, but simply an accumulation of epithelium in the ducts, portions were taken and planted in the same glands of three other puppies of the same litter. In none of these did cancer make its appearance, even at a period long after that at which the disease appeared in the two of the first group that were experimented upon. One of the first three became distinctly cancerous in eight months, the other in a little over ten; while of the three last pups, none showed any symptoms after a lapse of more than two years.

What, we might ask, is the infecting material in the case of cancer? Is it the fluid from the diseased part, the connective tissue debris, a new cell, or the epithelium? That it is not a new cell may be answered at once; for no new special cell belongs to the life history of cancer. On the other hand, it seems almost a certainty that the *materies morbi* for the spread of the disease is not from the connective tissue in any way. Take the example of cancer in the breast once more, and we find that the axillary glands may be very much enlarged at a period when the most careful and repeated microscopic examinations of the mamma reveal no evidence whatever that its connective tissue is breaking down. The most searching examinations also fail to show that anything likely to have come from the connective tissue can be found in the lymphatic channels. It seems, again, that it cannot be due to any fluid, pure and simple, unless it contains floating in it some solids from the cancer-growth. In the experiments performed on the pups, where a portion of the cancer was taken free from epithelium in alveolar spaces in the tissue, no cancer was produced by engrafting. Now, it can hardly be supposed that a section from the same tumor would not contain the same juices throughout, although the arrangement of the cells and fibrous tissue differed in different portions. That it is in all probability the epithelium that is the active agent in causing the appearance of cancer in neighboring glands seems to me almost to follow from what I have next to state. In no case have I been able to find any evidence of enlargement in the lymphatic glands prior to the date at which, when the cancer is removed, free epithelium can be found wandering, so to speak, in the connective tissue. When this stage has been reached, and not till then, have I been able to find in the lymphatic vessels or glands anything resembling the epithelium found in the alveoli of a cancer. After this date, however, such wandering epithelium can be detected.

One more remark, and I have done. There seems to be some strange change going on in the tissue of a part which is becoming cancerous; and up to a certain point it is benign, beyond this malignant. It is, in other words, acquiring a new power and existence of its own. For a certain period the ovum is only a mass of protoplasm endowed with vitality; by and by it comes to have a separate life of its own, independent of the parent, and possessing peculiarities which it in turn is capable of transmitting. It does not appear that the epithelium in a cancer has acquired infecting power until the alveolar condition has been attained, or, at all events, until the epithelium is found in the connective tissue.

THE RELIEF OF TOOTHACHE.—Dr. Kenneth W. Millican suggests the following convenient method (*British Medical Journal*): "It is a modification of a method recommended by Professor Babaieff to the Caucasian Medical Society. Melt white wax or spermaceti, two parts, and when melted add carbolic acid crystals, one part, and chloral hydrate crystals, two parts; stir well till dissolved. While still liquid, immerse thin layers of carbolized absorbent cotton-wool, and allow them to dry. When required for use, a small piece may be snipped off and slightly warmed, when it can be inserted into the hollow tooth, where it will solidify. The ease produced by this simple method is really very great."

Progress of Medical Science.

TREATMENT OF FISTULA IN ANO.—Dr. Poingt claims that any fistula amenable to treatment by the elastic ligature may be cured by simple drainage of the fistulous tract. The drainage-tube is inserted by means of a stylet passed up the tract from the external opening. At the end of two or three weeks the drainage-tube falls out, after having destroyed the superficial wall of the fistula. A granulating surface of small extent is left, which rapidly heals by cicatrization. The procedure is wholly painless, and the patient may pursue his ordinary avocations during the entire course of the treatment. The operation is never followed by any of those serious complications sometimes seen after the cutting operation.—*Le Courrier Médical*, July 28, 1883.

TREATMENT OF PSEUDARTHROSIS OF THE TIBIA.—Dr. F. Guérmonprez relates in the *Bulletin Général de Thérapeutique*, July 30, 1883, a case of ununited fracture of the tibia cured by means of successive slight irritations of the opposing surfaces of bone, occasioned by the moderate use of the member. He concludes that in cases of this kind walking within appropriate limits is not injurious, and may even be conducive to a cure. The limb is to be steadied during use by means of stiff, well-fitting splints closely bandaged to the parts.

DECOCTION OF LEMON IN THE TREATMENT OF INTERMITTENT FEVER.—Dr. Maghen states in the *Giornale di Clinica e Terapia* for March, 1883, that he has obtained excellent results in the treatment of intermittent fever and the malarial cachexia by a decoction of lemons. The remedy was recommended to him by another physician, and he tried it first in some old inveterate cases, without, however, anticipating any remarkable results. The decoction is prepared as follows: A lemon, as fresh as can be obtained, is cut up into small pieces and put into an earthen vessel. Three glassfuls of water are poured in and boiled down to one glassful, which is then to be strained through a linen cloth and cooled in the open air. As a result of his trials of this remedy, the author arrives at the following conclusions: 1. Decoction of lemon, employed in malarial affections, gives results equal, and even superior, to those obtained from quinine. 2. It not only cures when quinine does, but even in those cases in which the latter remedy is useless. 3. It is equally effective in cases of chronic malarial cachexia. 4. It presents none of the disadvantages of quinine (irritation of the mucous membranes and tinnitus aurium). 5. Its administration is possible even in catarrhal conditions of the digestive tracts. 6. In addition to these advantages it possesses the further recommendation of cheapness. In commenting upon these conclusions, Dr. Kahn (*Bulletin Général de Thérapeutique*, July 30, 1883) states that the natives of French Guiana employ with success the decoction of lemons to ward off a threatened attack of chills and fever.

PRIMARY PEPTONURIC DIABETES.—Dr. Quinquard describes in *La Tribune Médicale* of August 5, 1883, a morbid condition, characterized often by emaciation, thirst, polyuria, and marked cachexia. Examination of the urine shows it to be of low specific gravity, abundant in quantity, not precipitating by heat or nitric acid, but deviating the plane of polarization to the left. Millon's reagent produces an intense red coloration, and a precipitate is thrown down by tannin, mercuric chloride, chlorine, and iodine. All these reactions denote the presence of peptones. The urine should be examined immediately after having been voided. The subjects of this condition present the same clinical picture as do those suffering from diabetes mellitus. The cause is not always easily determined, though a sudden chill or lively emotions may be mentioned as probable causes. There is a defect of assimilation, from which ensues a general

disease, a true dystrophy. It is well known that peptones are excreted by the kidneys under certain circumstances, the condition being then a secondary peptonuria. But the cases seen by the author are stated to have been instances of primary peptonuria. There is another condition also in which peptonuria supervenes upon true diabetes mellitus, but this is very different from the disease under consideration.

ANTISEPSIS IN OVARIOTOMY AND BATTEY'S OPERATION.—In an article with the above title, appearing in the *Virginia Medical Monthly* for August, 1883, Dr. Battey presents the records of eighteen consecutive cases of ovariectomy and of Battey's operation. They were performed under strict antiseptic precautions, including the spray, and all terminated in recovery. While not believing that the spray or the use of carbolic acid in general is essential to success, the author thinks that weak solutions can do no harm, and that their use may serve to guard the patient against any slight imperfections in the details of cleansing. And he therefore says that he is content to hold them as valuable assistants in abdominal surgery until their utter uselessness has been more conclusively shown. He further says that his experience has been uniform upon one point, namely: that when a patient has been operated upon at her home and left to the care of her family physician, convalescence has been unduly slow and unsatisfactory.

RECTAL ADMINISTRATION OF SALINES.—The following is the plan pursued by Dr. W. Jaworski in the treatment of disorders of the large intestine (*Memorabilien*, July 16, 1883): In cases in which there is irregular action of the bowels (constipation alternating with diarrhoea, or either of these conditions alone), when palpitation reveals the presence of impacted fecal matters and points of tenderness in the large intestine, and when the stools are mixed with mucus, he uses injections of a two and a half per cent. solution of soda of increasing temperature. An ounce and a half of ordinary crystallized soda is dissolved in three pints of warm rain water, and as much of this as possible is injected into the rectum, and retained by the patient for about five minutes. This is done every day, at least five injections being practised. They have the effect of cleaning the bowel of the masses of mucus. Then at least five more injections are given of the same solution, with the addition of a tablespoonful of common salt. These are given only every second day. After the rectum has been well cleaned, and little or no mucus is seen in the stools, the author uses enemata of warmed Karlsbad water, to every bottle of which, in cases of obstinate constipation, a tablespoonful of sulphate of soda is added. It is advisable during the treatment by enemata, to intermit for several days at a time in order to ascertain what progress has been made. Where there is atony of the rectum it is well to give injections of pure cold water, with or without the addition of common salt, and these are recommended also in the after-treatment. The diet should consist chiefly of meat and milk. In cases of habitual constipation, without catarrh or any apparent lesion of the large intestine, the author begins at once with enemata of sulphate of soda. The first injections are warmed, and contain about two tablespoonfuls of Glauber's salt in three pints of water. Instead of pure water, the salts may be dissolved in Karlsbad water with advantage. Each day the water is used colder, and chloride of sodium is usually added to it. A mixed diet (excluding starchy food) is ordered. When a clearing-out of the entire intestinal tract is sought, a glass or two of cold soda-water, with a little sour wine, is ordered. In feverish conditions, or when the stools contain streaks of blood, very cold solutions of Glauber's salt and chloride of sodium are advised. The advantages of the rectal administration of the salines are summed up by Dr. Jaworski as follows: 1. The patient is spared the disagreeable taste and the nausea so often following the taking of salines. 2. Such a strict regulation of the diet is unnecessary, and the

salts may be given even after a full meal. 3. The entire intestinal tract is not uselessly irritated, but the remedy is locally applied, and acts for the most part only on the diseased portion. 4. The dose can be more easily regulated, for when salines are given by the mouth, the amount that reaches the rectum or acts upon it in any way is a very uncertain quantity. 5. The local effects of heat or cold may be obtained, together with those of the medicines employed, when the latter are given by enema.

CEPHALALGIA OF ADOLESCENCE.—Dr. R. Blache describes a form of headache, of not infrequent occurrence in individuals of either sex from twelve to eighteen years of age, which he thinks is deserving of recognition as a distinct morbid entity. It is not constant, but recurs with great frequency, and is evidently increased by mental effort. The pathogenesis of this form of cephalalgia he sees in a complex of altered nervous function, disturbances of the circulation, intellectual effort, and insufficient aëration acting during the period of puberty. The treatment consists in an active life in the open air, the use of suitable glasses if there are any defects of vision, and, above all, the absolute cessation from all mental work during a prolonged period.—*Archives Médicales Belges*, July, 1883.

RETARDED UNION OF FRACTURES IN DIABETES.—In a communication addressed to the Academy of Medicine of Paris (*Bulletin de l'Académie*, July 29, 1883), Dr. Verneuil related the histories of several cases in which the union of fractures occurring in diabetic subjects was delayed, imperfect, or entirely absent. He referred to the theory of Bouchard, who classes diabetes among the disorders attributable to a retardation of the nutritive processes, and he thought that the cases observed by him were corroborative of this view. For the repair of wounded tissues is a form of nutrition, and any delay or fault in the reparative process implies a corresponding defect in the function of nutrition.

A CASE OF AMAUROSIS TREATED BY THE PERCUTEUR.—There is a little instrument, called the percuteur, recently invented by Dr. Mortimer Granville, by means of which a number of taps in regular and very rapid succession, and of varying intensity, can be given to any part of the surface of the body. Dr. Granville's theory of pain is that it is due to abnormal vibrations in a sensory nerve, and he explains the action of the percuteur in the cure of pain and of other symptoms by the theory that it induces a new and orderly set of vibrations in the nerves to which it is applied. Dr. W. Carter relates a case in the *Liverpool Medico-Chirurgical Journal* for July, 1883, in which the application of this instrument was followed by the most striking benefit. He is not prepared to accept Dr. Granville's theory of the action of the percuteur, nor is he inclined to assert positively that his case was cured by it, but leaves his readers to form their own conclusions. The patient was a man forty-five years of age, of excellent physique, free from any taint of syphilis or hereditary disease. About five weeks previously he was seized, without any premonitory symptoms, with a headache, located chiefly in the temples. The following day the pain was worse, and was accompanied by a little chilliness and general malaise. Several times during this day he observed a dimness in the right eye. On the next day he was forced to go to bed by the severity of the pain in the head. On the fourth day he was totally blind, and experienced great pain in the eyeballs when moving them from side to side, but not when he moved them up and down. By the end of the week all pain in the head and eyes had disappeared, but the amaurosis persisted. Several careful ophthalmoscopic examinations revealed no abnormality. The pupils were dilated and but slightly responsive to light. Leeches were applied behind the ear, and iodide of potassium and solution of the perchloride of mercury were administered internally. His condition

remaining unchanged, Dr. Carter directed that the percuteur be applied daily for five minutes to the eyeballs and temples respectively. At the end of a week the patient was able to pick his way through the ward without assistance, and at the expiration of a month was able to read coarse print and to walk briskly through a crowded street without a guide. He was again submitted to an ophthalmoscopic examination, when it was discovered that he had commencing cataract in each eye. The author, while feeling no more certain that this lesion was a result of the treatment than that the restoration of sight was attributable to the same agency, is yet inclined to think that the rapidly successive taps on the globe of the eye so modified the structure of the lens as to lead to the production of cataract.

THE VARIATION AND DISAPPEARANCE OF CARDIAC MURMURS.—Dr. E. Hyla Greves writes in the *Liverpool Medico-Chirurgical Journal* for July, 1883, concerning the variations and changes so often observed in certain cardiac murmurs, dependent on definite organic lesions. He relates the histories of several cases, from a study of which he draws the following conclusions: 1. Although murmurs are among the most constant of the physical signs of heart disease, still their presence does not necessarily indicate the existence of incurable lesions, nor their absence that such lesions are not present. In forming a correct diagnosis and prognosis of any case, therefore, too much reliance must not be placed upon the presence or absence of murmurs, but other symptoms must receive careful consideration, for often on them alone is it possible to form a correct diagnosis. 2. The presystolic murmur of mitral stenosis, the most typical of all murmurs, occasionally disappears, the lesion still remaining. Mitral regurgitant murmurs, when due to simple relaxation of the heart's muscle, and dilatation of its cavities and orifices, as in chlorosis and general febrile conditions, in most cases completely disappear under appropriate treatment. 3. Tricuspid regurgitation is occasionally a temporary condition, due to bronchitis, etc., and when the cause is removed this condition is recovered from, as is indicated by the disappearance of the murmurs. 4. Aortic systolic murmurs, due to a permanent lesion at the aortic orifice, may undergo changes in their intensity, but never completely disappear. 5. Aortic diastolic murmurs in certain extremely rare cases have been known to disappear. In these cases a systolic aortic bruit is always present and remains persistent, thus indicating the existence of the lesion. 6. Pulmonary systolic murmurs are persistent when due to an organic lesion; but if non-organic, may disappear temporarily or permanently.

REMOVAL OF WENS WITHOUT THE KNIFE.—Dr. Carreaux removed a fatty tumor the size of a pigeon's egg from a young girl's foot by the following method, recommended to him by an old lady of his acquaintance. Frictions were made three times a day over the tumor by a mixture containing equal parts of hydrochloric acid and turpentine. The application was prolonged until the patient complained of a severe smarting. Then a plaster of hyoscyamus and mercurial ointment was spread over the part. The applications were made in this manner for eight or ten days, when signs of commencing inflammation appeared. They were then discontinued. A slight eschar formed at the most prominent part of the tumor, and being thrown off, left a small opening through which the contents of the tumor were gradually extruded. When the sac was empty the walls became adherent through inflammatory exudations, and the cure was complete in a month or six weeks. The author regards this method as of value when the patients dread the knife, and when the tumor is small, but advises against its employment in the case of large tumors, owing to the danger of septicæmia arising from suppurative inflammation of the walls of the sac.—*Journal de Médecine de Paris*, August 11, 1883.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 29, 1883.

THE PREVALENCE OF TYPHOID FEVER.

THE Sanitary Superintendent, Dr. Walter DeF. Day, has submitted to the Board of Health a report on typhoid fever as it at present exists in this city, which, though brief, contains points worthy the careful attention alike of the medical profession and the public. It is gratifying to learn that this disease is now being carefully studied by the sanitary authorities with a view to its causation, the degree of its contagiousness, and the prophylactic measures best calculated to control its prevalence; and although the report now before us is only preliminary, the importance of care in the disinfecting and removal of excreta is plainly shown. Where, in repeated instances, there being no sanitary defects to account for it, five or six cases have occurred in one family coincident with neglect in the disinfecting and removal of excreta and soiled clothing—these having been allowed to remain for hours, throwing off their exhalations to be breathed by the sick and well housed together—there appears to have prevailed either lamentable ignorance or gross carelessness in the use of simple preventive measures. The theory of typhoid fever being communicated through the discharges from a patient suffering with the disease is now generally accepted, and on this subject the public should be informed. It is clearly the duty of every medical man to do something more than advise disinfection in a general way. He should explain fully just what is necessary to be done, and the best manner of doing it if he would accomplish without exception the entire object of his mission.

The increase in the number of cases of typhoid fever daily reported to the Sanitary Bureau during the present season is assuming a grave importance. We learn from Dr. Day's report that during the month of July there were 93 cases reported, against 40 for July, 1882, and in August there were 244, against 96 in August, 1882, while to all appearance we shall probably have during the month of September some 300 cases, against 117 during the corresponding month of last year.

The question very naturally arises, To what is due this rapid increase of the disease during a season otherwise remarkably healthy, and in a city where so much has been done to improve the sanitary condition of dwellings and their surroundings? We do not remember the time when our city has been in a better condition as regards general cleanliness than at present, and yet cases of what is especially regarded as a filth disease are daily

increasing in frequency. May it be in any degree due to the scarcity of water and a consequent deficiency in the flushing of our house-drains and sewers? Is our drinking-water or the milk we use contaminated with typhoid poison, or are there meteorological conditions which we do not fully understand influencing the course and type of disease?

We find upon inquiry that our city is not alone the object of this visitation. We hear of the same disease existing on all sides of us in different portions of the country. Of the 250 cases reported to the Sanitary Bureau from September 1st to the 24th inclusive, we learn that 35 came from the country, and from almost as many directions. We also learn that on railroad and other works in different portions of our State, where large numbers of laborers are employed who live in crowded barracks, typhoid fever has appeared in a very serious form.

These facts seem to point to the conclusion that this tendency to enteric affections is largely influenced by some general atmospheric or telluric causes rather than to local conditions, and yet when such general tendency exists, the disease, whatever it may be, is sure to locate and spread among localities where cleanliness is neglected and sanitary arrangements are defective. Hence the importance of careful and thorough inspections, not only of places where typhoid fever has appeared, but all places where sanitary defects may be found, with a view to correcting these defects and preventing disease. The physician, if he will, can do much toward aiding the Board of Health in this work, by promptly reporting his cases, and giving all necessary instructions to the family in each case, in regard to disinfectants and the general sanitary care of the sick and well. He cannot too strongly insist on the importance of absolute cleanliness, the immediate disinfecting and removal of all excreta, and if he is not familiar with the most approved disinfectants and the method of using them, he should lose no time in acquiring the requisite information. The activity previously displayed by the Board of Health in combating small-pox and typhus fever, and the success which attended its efforts, give us reason to hope that the problem how to stamp out typhoid may yet be solved.

THE MEDICAL COLLEGES AT FORT WAYNE.

WE have received a number of letters from reputable physicians living in Indiana, regarding the medical institutions at Fort Wayne, in that State.

It appears that there have been two colleges in that city, the Medical College of Fort Wayne and the Fort Wayne College of Medicine. The former was the older, and during its six years' existence it made some effort to establish a good standard of education. Its ambition and prosperity were cut short, however, by the establishment of the Fort Wayne College of Medicine. The new institution was rejected by the American Medical College Association on the ground that it "taught immorality." It was subsequently declared a nuisance by the Mayor's Court of the City of Fort Wayne. Following this, there appeared an annual announcement of the college in question, with an "especial notice," which is at once so ingenious in character and elastic in function that we print it entire:

"Inasmuch as this college is *not* a member of the 'Association of American Medical Colleges,' the Faculty desires to have it explicitly understood that it is in no respect bound by any of the regulations of that association; that our requirements for an admission to a final examination for the degree are entirely within the control and discretion of the faculty, and not governed by any arbitrary dicta; and that these requirements are substantially as follows, subject to any *desirable alteration*."

The opportunities for "desirable alterations" are then succinctly enumerated.

Before opposition like this the Medical College of Fort Wayne, to its credit be it said, collapsed, the loss not being probably a great one to the higher educational interests.

In the present status of affairs, it is unlikely that the earnest student of medicine will travel to Fort Wayne for educational purposes.

FISH AS FOOD, AND THE UNITED STATES FISH COMMISSION.

In a lecture recently delivered by Dr. B. W. Richardson, at a meeting convened by the British Fish League, the speaker said that the elements required for the sustentation of healthy life were the flesh-building, the force- or heat-producing, the mineral, and the watery. Most fish contained all these necessary constituents, some more than others. Pollack held all the necessary qualities very equally balanced. But the strongest and most nutritive fish was sturgeon, which equalled in all the essentials the best flesh meats. The speaker thought it was a question whether fish could not be made generally as nutritive as flesh meats, and he suggested that the Government should institute an analytical commission on the subject.

We have sometimes wondered why the United States Fish Commission, with its numerous corps of learned professors, has not made some careful investigations into the exact food value of fish. Fish is certainly not so good a food as flesh, and never can be entirely substituted for it. It has more water than the ordinary meats, or than game, and contains more inorganic salts in proportion to the solids than flesh. Further, it has a small amount of non-nitrogenous matters, and its nutritive ratio is as 1.2 to 1, when the ratio in normal diet is about as 1 to 3½, and the ratio in beef is as 1 to 1½.

According to Landois, the nutritive constituents of the different kinds of foods are as follows :

	Beef.	Pork.	Fowl.	Fish.	Hens' Eggs.	Wheat Bread.
Water.....	62.	55.	73.	76.	73.5	41.3
Albumen.....	12.	6.	19.5	12.	13.5	6.3
Albuminoids.....	3.	5.	1.3	4.		
Non-nitrogenous....	20.5	33.	4.7	6.	12.	51.
Salts.....	2.5	1.	1.3	2.	1.	1.4

The analysis given of fish, however, can only be considered to represent a few kinds. There are great differences in food value among the various forms of fish. Some accurate chemical analyses would be of great interest in studying the question of food fishes. It is very well agreed that a fish diet may cause disease as well as support life, that some tribes seem to degenerate and others to thrive upon this kind of food.

HOW BEQUESTS TO HOSPITALS MAY BE DIVERTED
A CURIOUS case has just been decided in Chicago adversely to the claims of the Woman's Hospital of the State of Illinois, and the Chicago Hospital for Women and Children, and aside from this point, which would make it interesting to medical men, it is remarkable as illustrating the fact that the intentions of testators are often absolutely frustrated.

In 1876 Miss Julia R. Newberry died in Chicago, leaving a will, in which was the following provision: "In event I die unmarried, leaving my mother surviving, I devise and bequeath to her all my property, both real and personal, of every kind and nature, upon the express condition, however, that she devise by will, to be executed before receiving this bequest, so much thereof as shall remain undisposed of or unspent at the time of her decease, to such charitable institution for women in said city of Chicago as she may select." After the death of Miss Newberry, her mother refused to take the property subject to this condition, saying that this refusal made the will of no account, and claiming the property as the only heir-at-law.

Under these circumstances the Woman's Hospital of the State of Illinois, and the Chicago Hospital for Women and Children, each claimed that they were properly designated by Miss Newberry in her will, and asked that a trust be declared in the property in their favor.

Upon the trial the Court did not decide as to the legality of the claim of Mrs. Newberry, but decided that the hospitals had no rights, as the making of a will in their favor was a condition precedent to Mrs. Newberry's taking under the will, and as she refused to take there was no ground upon which to rest their claim.

It was also held that the bequest in favor of some institution for women was uncertain and could not be upheld, for it was a matter of doubt whether there would be any property left at Mrs. Newberry's death. The whole case is an illustration of the uncertainty which hangs about even an apparently plain provision in a will.

THE PROPHYLACTIC WORTHLESSNESS OF COPPER.

APROPOS of some recent correspondence on a theory advanced by Dr. Burq concerning the immunity of workers in copper from contagious diseases, it may be of interest to cite the views of Dr. Bailly upon the same subject. At a late meeting of the Academy of Medicine of Paris, this gentleman protested in vigorous terms against the theory of Dr. Burq, and denied that there was any prophylactic virtue at all in copper. In fact, he seemed to regard it as an excellent microbe stimulant, and to incline to the opinion that these invisible but deadly organisms waxed fat and strong under its tonic influence. He stated that at Bornel and Ercuis, in the valley of the Esche, and at the neighboring hamlet of Chambly more than five hundred workmen are employed in the manufacture of various articles from *alferide*, an alloy containing ninety per cent. of copper. Yet typhoid fever is almost endemic in this valley, while the neighboring plateau, where Chambly is situated, is practically exempt. Out of fifty-three cases of this disease seen by M. Bailly in this locality, twenty-six occurred among the copper-workers, and of four deaths, all were

among the workmen, who should, according to M. Burq, have been protected by the nature of their occupation. Similar facts were observed, he alleged, in the case of other diseases. In 1832 Chambly was decimated by the cholera, while Bornel, lying but a short distance away, escaped the visitation entirely. This would, at first sight, seem to be an argument in favor of the prophylactic value of copper; but, unfortunately for the theory, the *alfénde* works were not then in existence.

The communication, made by M. Burq to the Academy of Medicine a short time ago, attracted considerable attention, and his conclusions were widely copied by the public press on both sides of the water. The facts were convincing as far as they went, and the theory was so fascinating in its simplicity, and was fathered by so eminent an authority, that it speedily won its way to the hearts, if not the intellect of the people. It would be so easy to wear a plate of copper under the clothing, and then bid defiance to all epidemics. And the practice would, furthermore, have an immense advantage over that of carrying a buckeye in the pocket as a preventive of rheumatism, for it would rest on a scientific basis, and would have the very best medical endorsement. Indeed we are surprised that the vacuum in the advertising columns of our religious contemporaries, caused by Miss Lydia Pinkham's early demise, has not already been filled by testimonials of wonderful escapes from the measles of children wearing the copper pad. But we have not long to wait before the copper pad appears, or else our faith in Yankee enterprise is vain. M. Bailly comes too late with his cold, hard facts, and while perhaps he may succeed in dismounting Dr. Burq from his cupric hobby, he will never be able to convince the world at large that he has done so.

A DANIEL COME TO JUDGMENT.

A GREAT reformer has arisen; an instructor of purblind humanity in the ways of correct hygiene; a rebuker of his medical brethren. *The Popular Science Monthly*, supremely devoted to the inculcation of scientific truths, and the promoter of scientific habits of thought, is the medium whereby the lucubrations of this new apostle of medicine (as it should be) are communicated to the human race.

Our professor of the new gospel of *physic*—pardon us, we do not mean the nasty stuff which purges, and which he abhors, but the *art of healing*—is a vegetarian. Apparently under no circumstances and in no conditions would he recommend an invalid to eat meat. Here he has almost the entire weight of the medical profession against him, and the best physiologists; founded as are their beliefs on an experience which is overwhelming. He is nothing daunted by this, however, and advises even the debilitated and the consumptive to eschew a flesh diet.

Our hygienist is, moreover, bitterly opposed to all medicines. For the asthmatic a "cold bath" is the most reliable remedy in the attack; no internal medication should be used. The dyspeptic should under no circum-

stances resort to drugs, "which only momentarily help one disease by inducing another." We are pleased to see in the last *Popular Science Monthly* quite an effective criticism on this therapeutic nonsense, by Dr. J. R. Black. "Only a person of superficial knowledge," says Dr. Black, "of strong physique, and bigoted withal, who judges all others by his own personal equation, could discourse thus. Men and women will eat and drink, either with or without knowledge, what they ought not, and as a consequence the stomach rebels, and intense suffering ensues. Only a short time since I saw a woman who had been writhing every few minutes with terrible gastric cramps for ten hours. Clearly it was an attack of acute dyspepsia. To the suggestion of an emetic she replied that a vomit nearly killed her. But another paroxysm of cramp led her to exclaim, 'Well, anything for relief!' In a few minutes she threw up nearly a gallon of fermenting food that filled her chamber with the fumes of a fetid sourness worse than that of an August swill-tub. Half an hour afterward she fell into a calm sleep. If humans will eat and drink what they ought not, eating not for need but for pleasure, not as a means but an end, the physician's duty is clearly to relieve suffering by the removal of its immediate cause, as by an emetic or cathartic." To this argument, illustrated as it is by an incident which happens in the every-day experience of physicians, Dr. Oswald makes no effective reply. In fact, no reply is possible.

So in regard to the treatment of constipation. It is not true that all our patients can attain a cure of this morbid condition by *dieting*. Not all our consumptives are in a condition, even in the early stages, to start off on an overland journey afoot to California!

As for the treatment of spasmodic asthma, it is not the experience of physicians that the inhalation of a little stramonium smoke produces after effects "worse than the disease." If any have seen the "vertigo," "heart spasms," and the "violent headaches," which Dr. Oswald describes, we certainly are strangers to such symptoms. Nor in practice do we think that it would generally be easy to induce our aged asthmatic patients to try the cold douche, albeit the best remedy, according to our writer. It would be an easy matter to review all of Dr. Oswald's writings and mark here, "fallacy;" there, "crude and not proven;" there, "impracticable."

There is much in these papers that is clever and interesting, and there are important hygienic lessons, but all is sadly marred by the dogmatical and paradoxical temperament of the writer, who is nothing if not a little "cranky." If the latter term seem a little harsh, we defend ourselves by saying once for all that we deem any man a "crank" who vehemently opposes the common-sense judgments and experience of mankind.

THE ILLINOIS HEALTH BOARD AND THE AMERICAN MEDICAL ASSOCIATION.

In the last quarterly report of the Illinois Health Board the Secretary, Dr. Rauch, gives an account of his experience at the meeting of the American Medical Association, which, as he says, he deemed it his duty for several reasons to attend.

The reasons for his attendance were made manifest by a discussion which occurred in the section on State Med-

¹ See Forget's Physiology, vol. i., page 104, for an exhaustive study of this subject, and a fair statement of the advantages of a mixed over a purely vegetable dietary. The facts adduced are startling and unanswerable.

icine. At the conclusion of a paper by Dr. Johnson, members inquired how the reader could be a member of a mixed board and also of the American Medical Association. A spirited discussion of the question ensued, the propounders of the query not only holding that it was wholly inconsistent with the Code of Ethics of the American Medical Association, and that no one claiming allegiance to it could engage in licensing homœopaths and eclectics to practice without forfeiting its privileges, but implying that the tendency of the work of a board so composed was injurious professionally. Other members of the section strenuously opposed these views, and cited the admitted results of the board's labors as a sufficient refutation of the implied strictures. The chairman of the section, Dr. Pratt, finally disposed of the technical question by referring to the formal action of the Association when the same point was sought to be made against himself. Some years ago, in the preparation of a bill similar to the Illinois Medical Practice Act, he had, he said, met in a convention of representatives of the different schools in Michigan, including homœopaths and eclectics. For this he had been arraigned on a charge of violation of the Code. The Association then held that the Code of Ethics could not be violated by any action of a member which was necessary to the discharge of an official duty under the law, and that the fact of membership on a representative board did not come within the purview of the Code of the Association governing the professional relations of medical practitioners.

The decision of course settled the case of Drs. Johnson and Rauch. But it is apparent that the decision was really a concession forced upon the Association, and that it is not consistent with the stand which that body claims to assume. For what right has a regular Association physician to take a position where his official duties force him into consultation and communion with homœopaths! And one might very easily ask why the Association, if it excuses Dr. Rauch, should not also excuse a physician who consults with homœopaths in the discharge of a professional duty under the moral law, which many have thought more obligatory than the enactments of legislatures.

NOW IT IS FIBRINE AND NOT FAT-CRYSTALS.—Dr. R. Gregg, of Buffalo, has been conducting some experiments on bacteria, and publishes the following remarkable summary of his labors: By boiling a quantity of healthy blood he obtained all the forms of bacteria. Then, with some pure fibrine obtained from a washed clot of blood and boiling it, proving that it was the threads of fibrine broken up into pieces and granules that gave the bacteria, the same results were obtained. Next, some blood was obtained and rotted under warmth and closely watched for two months, and here again the forms were obtained that the fresh-boiled blood gave. From these experiments Dr. Gregg concludes that all the bacteria of disease are forms of fibrine, and for the general good requests all investigators to repeat the experimental work and report to the public the results of such investigations.

PROFESSOR BUDGE, of Greifswald, has recently celebrated his fiftieth jubilee. Numerous honors and congratulations were bestowed upon him.

News of the Week.

BIRTHS AND DEATHS IN NEW YORK CITY AND ITS TENEMENT HOUSES.—Colonel Clark, Secretary of the City Health Board, made a statement recently before a Committee of the Legislature with reference to the excess of deaths over births in this city. He said the reason the statistics of deaths appeared to be so much larger proportionately than those of births was because there was no system by which a perfect registration of the births in the city could be obtained, and that one-third of the births at least were not registered. This fact accounted for the erroneous statement, made before the committee and frequently published, that the number of deaths exceeded the number of births in the city. The tenement-house population of the city—that is, the number living in buildings occupied by four or more families—aggregated eight hundred thousand, or a trifle more than one-half the entire population. The average number of tenement houses erected annually during the past three years was fifteen hundred. The city in its sanitary government was in advance of any city in the world, and it was also freer from small-pox and other contagious diseases than any other large city, and for that reason. Tenement houses were not so healthy as they might be, but their condition had been very greatly improved during the past few years, as property-owners found it beneficial to keep them in good condition, and now co-operated very generally with the Health Department authorities. The rules adopted here in relation to the plumbing of new buildings were now being adopted very generally in all the large cities of the country.

PROFESSOR ZEISSE, of Vienna, Physician to the General Hospital, has been raised to the rank of nobility, upon the occasion of his retirement from active work. Zeisse has made many contributions to syphilology.

DR. BOIS-REYMOND'S JUBILEE.—The twenty-fifth anniversary of Dr. Bois-Reymond's Professorship will be held in Berlin, October 25th. A bust of the eminent professor will be unveiled and a large number of his pupils will present commemorative scientific papers, which will appear in his *Archives*, forming a Jubilee volume.

KAIRIN, THE NEW ANTI-PYRETIC.—This drug has finally been put upon the market by a German firm, the price being 200 marks per kilogram, which is very much cheaper than quinine. Dr. Knipping, of Neuwied, has reported a successful experience with kairin in a case of puerperal fever.

MURDER OF A WESTERN PHYSICIAN.—Dr. A. B. McKune, of Council Bluffs, Ia., was shot and instantly killed by one Dr. E. D. Cross, of the same city. Dr. McKune was a well-known physician, member of the State and local Medical Societies.

DEATH FROM AN OVERDOSE OF MORPHINE.—Joseph W. Pilkington, a medical student, died a few days ago in this city from morphine poisoning. He had been in the habit of taking morphine recklessly to control a malarial cephalalgia from which he frequently suffered, and it is supposed that he took too large a dose at last. It is not thought that the self-destruction was intentional, as there

was no apparent motive for suicide. Mr. Pilkington was twenty-two years old. He was a student in the Bellevue Hospital Medical College, his home was in Sedalia, Missouri.

SMALL-POX is reported to be prevailing to a large extent among the laborers on the Georgian section of the Canadian Railroad.

AN ANTI-CHOLERA PILL.—Dr. Fonquet, of Cairo, asserts that the following prescription is efficacious as a prophylactic against cholera :

R. Asafetid.,
Opii,
Camphor,
Papav. niger....., āā .06 gramme.
M. Ft. one pill.

THE MICROCOCCI OF CHOLERA.—Dr. Stephen Kartulis, Physician to the Greek Hospital at Alexandria, has found minute round and oval cocco-bacteria in the blood and discharges of cholera patients, also in some of the filthy drinking-water used in the infected districts.

DR. TOMSA, of Kiew, has been appointed Professor of Physiology at Prague.

AUSTRIA has in its seven universities 2,418 medical students. United States has in about ninety medical colleges some ten thousand students.

THE RUSSIAN CONGRESS OF PHYSICIANS AND NATURALISTS held its annual session at Odessa, beginning August 18th.

THE PARASITE OF YELLOW FEVER.—Dr. Dominga Frieze, a Brazilian physician, thinks that he has discovered a parasite in the blood of yellow fever which is the cause of the disease. Animals inoculated with it died of yellow fever.

THE COLLECTIVE INVESTIGATION OF DISEASE.—The collective method of investigating disease, which has been pursued with so much earnestness in England, has been adopted by the Berlin Society for Internal Medicine.

THE NATIONAL LONGEVITY UNION is the modest title of a sanitary society, which, says the *Medical and Surgical Reporter*, has been recently organized in Erie, Pa.

MEDICINE IN NEBRASKA.—We have received a catalogue containing the annual announcement of a new medical college at Lincoln, Neb. The educational opportunities are most comprehensive and inviting. There is no charge for tuition, and there is (or was) a regular, a homœopathic, and an eclectic faculty.

THREATENED EPIDEMIC OF TYPHOID FEVER.—The number of cases of typhoid fever in this city continues to increase weekly. The possibility of an epidemic is to be borne in mind.

DR. N. SAPOLSKI, an obstetrician, of Moscow, died recently of septicæmia contracted while attending a case of childbirth. He was one of the editors of the *Medizinskoje Obosrenje*, a monthly journal published in that city.

INSPECTION OF FURNISHED ROOMS IN PARIS.—The police department of Paris has, at the request of the Municipal Council, instituted a service of inspection of furnished lodgings. Five regular inspectors and four

substitutes have been appointed at a salary of \$600 per annum for the former and \$25 per month for the latter. Each inspector must, on application, furnish a report upon the healthfulness of any lodging within forty-eight hours after the application is received. It is not stated whether the inspectors are medical men or not.

NIGHT MEDICAL SERVICE IN LEIPZIG.—The city of Leipzig has voted a yearly grant of \$250 to provide for a night medical service. The fee, to be paid by the city in case the patient is unable to do so, is set at the modest sum of \$1.50.

THE QUESTION OF CREMATION IN PARIS. — Acting upon the report presented by M. Brouardel, the Conseil d'Hygiène de la Seine has rejected the proposition to burn the bodies of those dying in time of epidemics, especially in an epidemic of cholera. The report stated that the interests of justice, as well as those of persons unjustly accused of poisoning, would be seriously compromised by the adoption of the practice of cremation, especially in the case of a cholera epidemic. It was said, further, that cremation would necessitate more handling of the bodies, and would therefore expose the living to greater danger up to the moment that the corpse was put into the furnace, than would interment. These objections were thought to overrule the obvious advantages of this method of the disposal of the dead, and the proposition was therefore rejected.

A RIVAL MEDICAL COLLEGE IN BEYROUTH. — The French have for some time been seeking to quietly extend their influence in Syria, with the view of ultimately assuming a protectorate over that country in the probable event of a disruption of the Ottoman Empire in the near future. As a further step in this plan, they are now about to establish a medical school with French professors in Beyrouth. One hundred and fifty thousand francs have already been expended in the acquisition of a suitable building and in the establishment of a chemical laboratory with all the necessary apparatus. The school is under the control of the French Government, and the professors have been selected from the Faculté de Médecine of Paris. The first session will commence in October.

WHOLESALE POISONING OF CONVICTS.—Over one hundred convicts in the Connecticut State Prison at Wethersfield were poisoned recently, it is supposed by eating some corned lamb. All those who ate of the lamb were seized with cramps and vomiting, while none were attacked who had not eaten the meat. The lamb was purchased of a Hartford butcher, and is thought to have been poisoned after leaving his shop. Ptomaines were probably the cause of the trouble. An analysis is to be made of both cooked and uncooked samples of the meat.

TYPHOID FEVER IN NEW YORK.—The city sanitary superintendent has made a report regarding the prevalence of typhoid fever in this city. He states that up to September 1st of this year, there were 539 cases, against 304 for the corresponding period last year. The disease is not confined to any particular locality, but is rather distributed generally over the city. Dr. Day calls attention to the neglect of proper disinfection in typhoid fever, as shown by the reports of the inspectors. The vital point in the sanitary treatment of typhoid fever is the effi-

cient disinfection of the clothing, bedding, etc., and whatever the board can do to impress this upon the medical profession of the city, particularly at this time, will be an important factor in controlling the disease during the approaching winter.

TYPHOID FEVER IN THE FRENCH ARMY.—An epidemic of typhoid fever of severe type has appeared in the military barracks of Mâcon, in the department of Saône et Loire, situated about forty miles from Lyons. The regiment quartered there has been transferred to camp at Cluny.

NOMINATIONS FOR OFFICERS OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At the stated meeting held Monday evening, September 24th, the following nominations for officers for the ensuing year were made: Dr. Austin Flint, Jr., nominated as uncompromising adherents to the Code of Ethics of the American Medical Association, T. Gaillard Thomas, for President; Charles A. Leale, for Vice-President; E. A. Judson, for Secretary; P. Brynberg Porter, for Assistant Secretary; Henry D. Nicoll, for Treasurer; and Drs. Charles McBurney, Richard H. Derby, Charles S. Wood, Charles Hitchcock, and Thomas H. Burchard, for Censors.

Dr. F. R. Sturgis nominated for President Dr. S. Oakley Vander Poel, who was willing to represent those who were in favor of sustaining the State Medical Society in its action concerning the Code. Other nominations were made as follows: for Vice-President, Dr. Andrew H. Smith; Secretary, Dr. Wesley M. Carpenter; Assistant Secretary, Charles H. Avery; Treasurer, Orlando B. Douglas; and for Censors, Drs. F. R. Sturgis, David Webster, Daniel Lewis, F. R. S. Drake, and Joseph W. Howe.

SIR WILLIAM MACCORMAC and **Dr. Lyon Playfair** are visiting this country.

A CANADIAN PHYSICIAN TO BE KNIGHTED.—It is understood that Dr. Grant, who has been the personal medical adviser of Princess Louise during her sojourn in Canada, will be knighted before the departure of the Princess for England.

YELLOW FEVER.—During the week ended September 15th there were eighteen deaths from yellow fever at Havana. Mr. E. E. White, United States Consular Agent for Ponce, Porto Rico, reports yellow fever prevailing in that city, especially among the foreign residents. Acting Assistant-Surgeon J. M. Main, of the Marine Hospital Service, reports one case of yellow fever in the City of Mexico, being an imported case. This, he states, is the second case which has occurred in the history of the city, the first case having occurred in 1865, a correspondent of the New York *Herald*, who died from fever contracted in Vera Cruz.

CHOLERA.—The Consul-General at Calcutta reports to the State Department that there were eleven deaths from cholera in Calcutta during the week ended August 4th, and twelve deaths during the week ended August 11, 1883.

During the week ended August 18, 1883, there was one death from cholera at Flushing, Netherlands.

In order to protect the Empire from introducing cholera now spreading in Egypt, the following measures have been adopted by the Government of Russia: In

the ports of the Black Sea, beginning June 29th: 1, to keep under quarantine for two weeks all the vessels arriving at any Black Sea port which have no certificate showing that they are safe from cholera; 2, to keep under quarantine for a week all the vessels coming, with certificate of health, from the Straits of Constantinople and from the Anatoly Coast, and also those having been under quarantine in foreign ports; and 3, to have quarantine exclusively at Odessa, Kertch, Theodosia, and Batum. In the Baltic ports, beginning July 14th: 1, not to admit to our Baltic ports any vessel coming directly from Egypt, which will have no certificate showing that they have been submitted to quarantine on their way; 2, to submit to sanitary investigation all the vessels coming from the other places of the northern coast of Africa; and 3, to submit to quarantine for six days all the vessels mentioned above in case of any doubt.

NEWS FROM PASTEUR.—M. Pasteur has sent a despatch to M. Dumas, stating that the commission sent to study the cholera in Egypt has made some very interesting observations of a novel character, and which tend to support his preconceived theories. He promises to communicate the details by letter.

PRINCE BISMARCK AND HIS MEDICAL ADVISERS.—An item is going the rounds, taken from the *Allgemeine Wiener Medicinische Zeitung*, which shows the discomforts to medical men of waiting upon German princes. It appears that Bismarck has never cherished any feelings of regard for his medical attendants; at any rate, he has never given expression to them, and it has been his constant habit to dismiss them whenever the fancy took him. It has often enough happened that he has discharged a practitioner of ordinary medicine to take up with a "homœopath," and sometimes to have both kinds in attendance at the same time. As he has said, "The method of treatment is of less consequence to him than the result." Sometimes he has fixed a time for his attendant within which he has required to be cured, or at least rendered fit for work. If the result has met the requirement, the patient has been content, but he has never had a word of acknowledgment or thanks for his medical adviser. When he was Deputy in Frankfurt he was attended by the then Regimentsarzt, now Director of the Imperial Health Office, Dr. Struck. When he was first in Friedrichsruh, Dr. Cohn, of Hamburg, was his attendant. When in Varzin he had a third. In Kissingen he had consulted Dr. Diruf. His wife is a believer in homœopathy, as well as a trafficker in a nostrum (made from magpies' wings) for the cure of epilepsy, and for some reason—perhaps influenced by his wife—he was for several years under treatment by professors of the "School of Homœopathy." Three years ago he returned to the rationalists, and consulted Professor Frerichs, whom he had consulted many years before; but within a short time he had made another change, and called in the professional man under whose care he now is. The present favorite is a Dr. Schwenningen, of Munich. This individual is a young man, thirty-three years of age, who, starting with brilliant prospects, has already succeeded in shutting himself out from relationships with most respectable families in consequence of

some indiscretion in connection with the wife of another medical man, one result of which was that both parties suffered a term of imprisonment. Bismarck, however, requires only medicine from his doctor, and the young man found his moral, or immoral, behavior no bar to the Prince's favor.

Bismarck suffers from sciatica and tic-douloureux; also from various gastric troubles, the result of his indiscretions.

THE AMERICAN PUBLIC HEALTH ASSOCIATION will hold its eleventh annual meeting at Detroit, Michigan, November 13th, 14th, 15th, and 16th. The following are the subjects chosen for special consideration:

1. *Malaria*.—Its etiology and the methods for its prevention in localities or in persons; its American history; its specific particles; its origin; the conditions of its pervasion; its laws of extension etc.

2. *Foods*.—Their adulterations; healthy or deleterious modes of preservation and the function of legislation in regard to them. Ascertained facts as to adulterations in this country. Facts as to canned goods, condensed milk, artificial butter and cheese, prepared meats, etc.

3. *Vital Statistics*.—Methods and results; defects apparent. How far foreign modes of tabulation are to be followed. Systems of collection and classification. Race vitality and the care of population as indicated by statistics.

4. *The Control and Removal of all Decomposable Material from Households*.—The mechanical laws, constructions, and appliances relative thereto. The construction of all inside pipes and their connections, their traps and siphonage, flushing, ventilation. How they shall be connected with out-door receptacles and yet be free from ill effect.

Reviews and Notices.

A SYSTEM OF SURGERY, THEORETICAL AND PRACTICAL, IN TREATISES BY VARIOUS AUTHORS. Edited by T. A. HOLMES, M.A., Cantab., Surgeon to St. George's Hospital, and J. W. HULKE, F.R.S., Surgeon to the Middlesex Hospital. Third English Edition. In three vols. New York: Wm. Wood & Co. 1883.

With the lapse of twelve years since the last edition of Holmes' System, numerous and important advances have been made in the science and practice of surgery. Within the period named new principles have been established and many questions heretofore considered of little moment in their bearings upon the salvation of life and limb have invited such extended discussion and called forth so many facts of experience that the conclusions based thereon have virtually marked the points of new and radical departures in treatment. Among these advances we may notice the influence which the antiseptic treatment of wounds has had upon the statistics of all operations, but particularly upon those in dangerous localities, and usually believed to be attended with extraordinary risks. Whatever may be the belief in the influence of antiseptics, in whole or in part, every progressive surgeon has learned the value of the cardinal principles of cleanliness, local disinfection, and free drainage. In the volumes before us these principles are duly considered, and the different points in dispute are very judiciously presented. The same may be said regarding other subjects of equal importance in their bearings on surgical operation. Those, for instance, connected with abdominal

tumors and other affections of the abdominal cavity, nephrectomy, rapid lithotripsy, operations upon joints; the pathology and treatment of injuries of the spine, and also the exhaustive discussion of the pathology of tumors, based more particularly upon the labors of the German pathologists, as well as a critical examination of the different advanced theories concerning the relations of septicæmia to pyæmia. Osteotomy as an operative procedure in the treatment of deformities is treated of at length, making, as it does, a new and decided advance over the more conservative and less effective methods formerly in vogue. So much for a general review of the marks of progress in an art as shown in this masterpiece.

The main features of the work are preserved, and the general arrangement is not materially altered. The several parts are naturally classified in regard not only to regions, but according to the apparatuses affected, giving the best possible opportunities for the thorough study of a given subject from a special standpoint. Many of the older authors have passed away, but in each instance their work remains and is brought up by accomplished editors to the present standard of positive advanced knowledge. It has been a pride with each author to do his part as well as possible, and nothing seems to be wanting to that end, taking into account the length of time required for the publication of the book and making allowance for such new facts as may have appeared in the meantime. Thus it naturally happens that the essay on gunshot injuries does not embody the experience of the late Egyptian campaign, a matter of no great importance, however, considering the other data upon which the article is founded. The latter remark would hardly apply in the same degree to the recent views on injuries of the back, which have been unavoidably omitted, and also as to many advances in the treatment of fractures, the remedying of deformities, and many operative methods which are peculiarly American. But the work as a whole, claiming as it does to represent the English school of surgery, is complete in every respect, and really stands without a rival. It is published in three volumes, instead of four as formerly, and presents an attractive typographical appearance. As it stands it represents the original and latest Holmes' System of Surgery, and contains the most recent views of the many distinguished authors who first contributed to its pages.

TRANSACTIONS OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA. Third Series. Vol. VI., 8vo, pp. 446. Philadelphia: P. Blakiston, Son & Co. 1883.

THE sixth volume of these transactions is unusually full of good scientific material and well represents the amount of working force in the membership of the College. It contains thirty-one original papers on different topics connected with medicine and surgery; all have a distinct practical bearing. It is published in its usual handsome style, and is a credit to the typographical art.

TRAINING SCHOOLS FOR NURSES, WITH NOTES OF TWENTY-TWO SCHOOLS. By W. G. THOMPSON, M.D. New York: G. P. Putnam's Sons. 1883.

THIS small pocket manual contains a general review of the nursing system in this country and abroad, with an account of the different American schools in active operation. It contains much useful information for all such as are interested in nurse-training.

THE PHYSICIAN HIMSELF AND WHAT HE SHOULD ADD TO HIS SCIENTIFIC ACQUIREMENTS. By D. W. CATHELL, M.D. Third Edition. 8vo, pp. 208. Baltimore: Cushing & Bailey. 1883.

THIS readable and instructive book has, in a very short space of time, advanced to its third edition. It is full of valuable suggestions regarding the proper pecuniary and social relations which should be maintained between physician and patient. Every physician who is in doubt as to the course he should pursue in obtaining business and keeping it, will read the work with much profit.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

Eighth Annual Meeting, held in Philadelphia, September 18, 19, and 20, 1883.

(Concluded from p. 328.)

THURSDAY, SEPTEMBER 20TH—THIRD DAY—MORNING SESSION.

THE Society was called to order by the President.

The first paper was by DR. H. F. CAMPBELL, of Augusta, Ga., on

MENSTRUATION AFTER EXTIRPATION OF THE OVARIES.

By general consent the influence of the ovaries in menstruation has long been recognized, and there was nothing in his paper which indicated that he would deprive them of their very important influence in connection with this function. Since the introduction of the operation of removal of diseased ovaries, it has been noticed that menstruation continues in some cases, and this has been variously attributed to habit, periodical plethora, and more recently to the fact that in removal of the ovaries the Fallopian tubes are not removed, and therefore the excitor of the menstrual nîsus remains. The ovaries, unquestionably, are the ordinary exciters of menstruation. But are they the only exciters to activity in the genital organs? Certain cases were cited in which menstruation, lactation, etc., had been excited by irritation at some remote point, as from a parotiditis, suckling in the unimpregnated woman, etc. These cases showed that certain influences acting through the nervous system were efficient agents in establishing uterine and ovarian action. Pain follows amputation, not in the stump but in some portion of the part amputated, and because the nerve-centre has been adjusted and adapted to originating such a sensation, and may not periodical congestion and revival of the function of menstruation be the result of an original endowment of the nervous system continued for a time, although the organs which are ordinarily the exciters have been removed?

DR. GOODELL, of Philadelphia, was disposed to accept the view that this bloody discharge which, in some cases, follows removal of the ovaries, may depend occasionally upon irritation of some nervous centre. He had not removed both ovaries without forced menstruation appearing within the first *five* days, and he had attributed this to irritation set up by enclosed nerves. He was inclined to think that some of the ovarian structure was left behind in those cases in which so-called menstruation continued for any great length of time. It is often difficult to get the stump of the pedicle down sufficiently low not to leave ovarian structure.

DR. EMMET reported a case in which he removed both tubes and ovaries from a woman at the Woman's Hospital, eighteen months ago, and she has menstruated thirteen times regularly since the operation; the only change in the function being that the flow has continued for only about three days, whereas before the operation it lasted a much longer time.

DR. GARRIGUES, of New York, said that in studying these cases the exception should always be borne in mind—namely, the possibility of the existence of three ovaries. One exceedingly interesting case was on record, where, after removal of two ovaries, the woman bore a child.

DR. T. GAILLARD THOMAS, of New York, said he had not much to say on this subject for several reasons. First, scientific men have not reached an absolute decision concerning the influence of removal of the ovaries on the cessation of menstruation, nor as to the influence of the ovaries in the production of menstruation. He had removed both ovaries between fifty and sixty times, had followed the cases as well as possible, and had the im-

pression left on his mind that when the ovaries are present menstruation is the rule, and after they have been removed menstruation is the exception. He regarded the bloody discharge which occurs after removal of both ovaries, as a metrostaxis. He did not recollect to have ever seen a case in which regular menstruation occurred for thirteen months after removal of both ovaries. In his cases the bloody discharge had been irregular, almost invariably of the character of a metrostaxis, usually disappearing after a short time, may continue five or six months, and in rare instances for one or two years. He had performed Tait's operation ten or twelve times, and there had been no difference in the result from that which followed Battey's operation. All the ovarian tissue is more likely to be removed in Tait's than in Battey's operation, and that is the probable reason why menstruation occurs less frequently after the former than after the latter. He thought Dr. Emmet's case might be accounted for as Dr. Garrigues had suggested, and sustained the suggestion by referring to a remarkable case occurring under his own observation, where he found a third ovary, having removed two, and allowed it to remain. He did not believe that the Fallopian tubes have anything to do with the excitation of menstruation; but with the performance of the function they have much to do. He had had but a single case in which there was a paroxysmal discharge of blood from the uterus after removal of both ovaries, and in that instance there was no such regular intervals as twenty-eight days between the times of the discharge, and there were none of the regular symptoms of menstruation.

DR. MANN, of Buffalo, said this bloody discharge might be explained, occasionally, at least, by the existence of some disease of the uterus or vagina overlooked. He had had five cases in which both ovaries were removed, and in one there was metrostaxis, which continued for some time, and finally when he again saw the patient in consultation an examination revealed distinct cancer of the vagina.

DR. CAMPBELL said, in closing the discussion, that he did not wish to deny that the ovaries are the common exciters of menstruation, but merely to suggest may it not, after removal of the ovaries, be due to other causes than habit, periodical plethora, or the fact that the Fallopian tubes are not removed, and depend upon the action of some nerve-centre endowed to act, and continuing to act, for the performance of a certain function although the chief organs through which it manifests this power have been removed?

The Society then adjourned to meet at 3 P.M.

THIRD DAY—AFTERNOON SESSION.

The Society was called to order by the President, and the first paper was read by DR. WILLIAM H. BYFORD, of Chicago, entitled

REMARKS ON CHRONIC ABSCESS OF THE PELVIS.

The author of the paper spoke first of the different situations in which pelvic abscess may occur, the most common being in the connective tissue of the broad ligaments. He then called attention to the directions in which the pus is likely to discharge, the impediments with which it may meet, and which may change entirely the course of the discharge; to the quality of pus, laudable at first, but when the abscess becomes chronic containing an admixture of serum and blood. Dr. Byford studied with minuteness and detail the changes which occur in the lining membrane of a chronic pelvic abscess, at first like that of an external ulceration and finally the cavity is lined with cicatricial membrane, and with the loss of the granulation character of the inner surface pus is no longer produced. The changes occurring in the lining membrane might afford an indication for treatment. When in the granulating condition the granulations may become exuberant, and form fungoid masses,

and if these redundant masses are not removed they will give rise to and maintain pyæmic fever. In a chronic abscess, therefore, remove all these masses by scraping the inner surface with a dull curette or finger-nail; and there is no danger in this procedure, because the walls of the abscess are usually quite thick. A case, the notes of which had been furnished by Dr. D. T. Nelson. Adjunct Professor of Gynecology, was then reported, in which this method of treatment was adopted with excellent results. Dr. Byford discussed at some length the methods of opening these abscesses, the difficulties encountered and the liability to refilling unless the cavity or cavities have a free opening for the exit of the pus.

DR. T. G. THOMAS, of New York, thought Dr. Byford had rendered great service by examining minutely the internal surface of these cavities and following out the peculiar changes which take place. There was one point to which he wished to refer in connection with the subject in general, and that was concerning the propriety of *searching* for these abscesses. This point had been brought forward by the late Dr. Brickall, Dr. Mundé, and Dr. Lyman. He wished simply to say on this point, that he believed there is no more dangerous process in gynecology than to go seeking for these collections of pus. If it can be ascertained by conjoined manipulation that there is pretty positively pus in the pelvic areolar tissue, if we know exactly where to look for it, and if it can be distinctly discovered, then, and only then, should this exploration be made; but made without pretty positive knowledge on this point, very evil results will follow. He had employed the aspirator only as a means of diagnosis, and regarded it as a bad method of treatment, because a *free* opening should be made. His routine practice had come to be to cut into the abscess freely with Sims' long knife, and insert a small glass tube provided with a perforated flange so that it can be secured in position with sutures. When the abscess is large he stuffs the cavity with tow saturated with iodoform, repeats it in twenty-four hours, and thus goes on until cure is effected. He had not had any experience in the use of the curette, as recommended by Dr. Byford.

DR. GOODELL, of Philadelphia, regarded the method of treatment by the use of the curette as novel, but thought it might be an admirable way of effecting a cure. In the majority of instances the cases of pelvic abscesses he saw were of long standing, and there were more or less of fistulous openings. His method of treatment was first, if there is an opening from above, to pass in a long uterine sound and see if there can be established a communication with the vagina. If so, an opening is made, a drainage-tube inserted, and in that way he had succeeded in curing many patients. Other plans which he had tried had been irrigation with solutions of permanganate of potash, carbolic acid, etc., and injection with a much stronger solution of carbolic acid than is used for purposes of irrigation. With reference to aspiration, he had occasionally resorted to it, and while he was not satisfied that it is very good, he did not think it is quite so bad as Dr. Thomas was disposed to regard it.

DR. SURTON, of Pittsburg, had seen Esmarch scrape out pelvic abscesses at his clinics in Kiel, and he thought that this clinic might be regarded as an exponent of the surgical clinics of Europe. But the curette was not used with the view of removing the long granulations mentioned by Dr. Byford.

DR. CAMPBELL, of Augusta, Ga., spoke of the special beneficial influence which the tartrate of iron and potassa exerted upon chronic abscesses. Except for the source from which the recommendation came with reference to curetting the inner surface of an abscess, he would not feel disposed to favor the plan.

DR. BYFORD, in closing the discussion, said that the chief purpose of his paper was to call attention to a few points, and especially to the changes which take place in the lining membrane of chronic abscesses.

DR. G. J. ENGELMANN, of St. Louis, then read a paper on

ERGOT: THE USE AND ABUSE OF THIS DANGEROUS DRUG.

He believed that it is never necessary to use ergot in obstetrics. The use of the drug he would limit to the non-pregnant womb. It is not the question how it may be used, but the fact that it is used very generally, and its bad effects are not appreciated which makes it desirable that it should be stated authoritatively that the drug does much more harm than good and that its use should be discarded entirely.

DR. JOHNSON, of Washington, said that in his study of this subject he had been made aware of the fact that ergot is not used by physicians so generally and to the extent which he once thought it was, or to the extent which Dr. Engelmann says it is used. He had not found physicians who use the drug in the first stage of labor and thought that such a statement was erroneous.

DR. CAMPBELL invariably gave ergot after the birth of the child, and believed that it was important, and should almost always be used after the administration of chloroform.

DR. ALBERT H. SMITH, of Philadelphia, regarded the use of ergot in obstetric practice as an unmitigated evil. He did not believe that it is needed under any circumstances, and is always capable of doing harm, and generally does do harm. Its use in the third stage of labor might not be reprehensible, but in only a very few cases could it be used with benefit.

DR. ELWOOD WILSON, of Philadelphia, was astonished that Dr. Engelmann should recommend the banishment of ergot from obstetric practice. He doubted very much if any man present would be willing to approach a case of placenta prævia without the use of ergot. He had seen thirty-two cases of placenta prævia, and had used ergot liberally and with excellent results. He was also surprised to hear Dr. Engelmann state that ergot was of no use in post-partum hemorrhage. Dr. Wilson regarded it as of immense use in this complication of labor. The difficulty is that the ergot is given too late and in too large doses. He regarded the use of ergot in the third stage of labor as very important, and had it at his command in all cases.

DR. ENGELMANN said he feared he had been misunderstood. He did not mean to discuss the possible limits for the use of ergot, or refer to a scientific distinction for the proper indications for its use. He meant simply that it is a dangerous drug, does a vast amount of mischief, and from the fact that it is a powerful factor in stimulating uterine contraction, other measures less dangerous and which will accomplish the same end with equal efficiency should be substituted for it.

The following paper was read by title:

A THEORY TO EXPLAIN THE RELAXATION OF THE VAGINA AND PERINEUM DURING LABOR,

by DR. JAMES R. CHADWICK, of Boston.

DR. GOODELL, of Philadelphia, offered complimentary resolutions concerning the efficient services of the retiring treasurer, Dr. Paul F. Mundé, which were unanimously adopted.

THE PRESIDENT then introduced the President-elect, DR. ALBERT H. SMITH, of Philadelphia, who made a few appropriate remarks, after which the Society adjourned to meet in Chicago on the last Tuesday in September, 1884.

BETTER THAN CONDURANGO.—It seems that New Orleans has been enlivened by the dean of a medical college there, who diagnosed and treated an ulcer of the gums about a young lady's tooth as cancer. Having failed to affect a cure, the case passed to a dentist, who extracted the tooth and let the "cancer" get well. A true victory for nature.—*St. Louis Med. Jour.*

Correspondence.

OUR PARIS LETTER.

THE THERAPEUTIC AND PROPHYLACTIC VIRTUES OF COPPER—REPORT OF THE FRENCH MEDICAL COMMISSION ON CHOLERA.

(From our Special Correspondent.)

PARIS, September 5, 1883.

AT the meeting of the Academy of Medicine of Paris, which was held on the 21st ult., Dr. Bailly read a paper giving an account of his experience of the therapeutic and prophylactic virtues of copper, as recommended by Dr. Burq, in various affections, particularly in cholera and typhoid fever, in which latter maladies the metal was considered to be a specific. Dr. Bailly is practising at Chambly, a small town in the Department of Oise, and I send you an abstract of his paper, which will at the same time serve, in some measure, as a reply to the interesting letter of Dr. Grace Peckham, headed "Copper and Cholera," and which was published in *THE RECORD* of August 18th. Dr. Bailly stated that the medication by copper was submitted by various physicians to serious trial during the cholera of 1866, and the results were so deplorable that it appeared that a method so deceiving was doomed, and that thenceforth it would be relegated to the arsenal of retrospective therapeutics as a mere object of curiosity. Dr. Burq, however, having revived the subject, Dr. Bailly thought it opportune to refute Dr. Burq's assertions with the following arguments:

At Chambly there are upward of five hundred persons employed in the manufacture of articles of "affénide," an alloy of which copper forms nine-tenths. If Dr. Burq's theories are correct, these people ought to enjoy a certain immunity against cholera or typhoid fever, but during the twelve years he has been in medical charge of the manufactory he has found that this is not the case. In an epidemic of typhoid fever Dr. Bailly attended 53 persons affected with the malady, of whom 26 were employed in the copper manufactory, and whose bodies were consequently well saturated with copper; of this number 4 died, all of whom were well "coppered." As regards cholera, Dr. Bailly states that in 1832 Chambly was decimated; of 1,400 inhabitants, 87 perished. In 1849, the new epidemic caused 47 victims. About a mile from Chambly, at a place called Bornel, there was not a single case of cholera, but this immunity could not be attributed to the virtues of copper, as at that time the copper manufactory that is now at the latter place did not then exist. Dr. Bailly enters into further details, which, for want of space, cannot be reproduced here. I must therefore refer Dr. Grace Peckham and others interested in the question to the Bulletins of the Academy of Medicine. I may, however, observe that Dr. Burq is perhaps singular in his theories, as I am not aware that metallothrapy, as he terms it, has made much progress in the profession, whether in this country or elsewhere, at least according to his ideal of the method. Indeed, the idea cannot be said to have originated with Dr. Burq; as, so far back as 1832, a Dr. Méray, of Paris, vaunted copper in cholera, and his report of the efficacy of the metal in this disease caused such a sensation that on inquiry it was found that the results were greatly exaggerated. No further importance was attached to the report and nothing more was heard of the marvellous effects of copper until about thirty years ago, when Dr. Burq took up the subject, and he has patronized it ever since, but, as I have already said, almost single-handed, for one never hears of its employment by any other practitioner, at least as recommended by Dr. Burq. At a previous meeting of the Academy of Sciences, Professor Vulpian was cited as one of the partisans of Dr. Burq's doctrine of metallothrapy, but as he was not present on the occasion he wrote a letter to the Academy repudiating such an imputation in the following terms: "No

well-established clinical fact has authorized me to admit the preservative or curative influence of copper in the treatment of cholera. If copper had any real efficacy, it is probable that it would have been made known in all the countries where cholera reigns, and particularly in those parts of India where the malady is endemic." On another occasion, taking part in a debate on Dr. Burq's method of metallothrapy in hysteria and other nervous affections, Professor Vulpian stated that he was not able to speak more favorably of it in these cases. Dr. Burq has responded to Dr. Bailly's communication at the Academy of Medicine, but as he has advanced nothing new or important, I need not trouble your readers any further on the subject.

According to official information received from Egypt, the cholera is evidently on the decrease. The Council of Hygiene at Alexandria reports that the number of deaths from the disease during the two months that have elapsed since the outbreak of the epidemic, amounted to twenty-seven thousand among the natives, and one hundred and thirty among the English troops.

The French medical mission that was sent to Egypt to study the nature of cholera has reported that the disease with which it had to deal was incontestably Asiatic cholera, and that the discoveries already made are of a nature that will tend to subvert almost completely the theories in vogue as to its origin and pathology.

The theory of the contagious and parasitic nature of cholera is evidently gaining ground in the profession, but the following incidents would seem to militate against either idea. Among the passengers of the *Peluse*, condemned to quarantine at Alexandria, was an infant that had lost its mother from cholera, but the infant was not in the least affected, and was still alive and well when the vessel reached Marseilles, although it had been suckled by its mother within a few hours of her death. When the body of a sheik who fell a victim to the disease at Cairo was being prepared for the funeral a number of fanatic Mussulmans rushed up and drank of the water with which the body was washed. If the contagious or parasitic nature of cholera is correct, surely few or none of these people could have escaped contracting the disease.

ON THE THERAPEUTIC EFFECT OF IODOFORM AND ETHER IN THE TREATMENT OF SORE THROAT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am tempted to ask a little space to call especial attention to two paragraphs of "foreign gleanings" that appeared in the last issue (September 8, 1883) of *THE RECORD*. They are the results of clinical observations on the part of experts, and their experience and statements confirm my own clinical observations and experience, published one year before either of the foreign contributions appeared in print.¹ While the title of my article refers only to ulcerated tonsils, the accounts of the cases cited gave full descriptions of sore and ulcerated surfaces of surrounding structures. The value of ether in combination with iodoform—to which I called attention—is now of additional interest to therapeutists. The testimony of the foreign observers forms a good addenda in support of my views and observations. "Ether in the treatment of sore throat: Professor Contalo employs an ether spray in the treatment of pharyngitis. Under its influence the temperature falls, the vessels contract, and the local condition is speedily improved. In two cases a fibrinous exudation was detached and not reproduced. Ether, according to the author, deserves a trial in pharyngeal diphtheria, not only as an antiseptic agent, but also because the pain is thereby greatly diminished, and the

¹ Clinical Observations on the Use and Value of Iodoform in the Treatment of Enlarged and Ulcerated Tonsils, *New England Medical Monthly*, June 15, 1882.

taking of nourishment facilitated." "A method of hastening the anæsthetic action of the ether spray: Dr. Vidal, at the Hôpital St. Louis, in Paris, shortens the duration of the process of congelation by the ether spray in the following manner: Making a slight prick with a needle at a point upon which the spray is directed. The little puncture made at this time excites a reflex constrictive action of the vaso-motor nerves, the blood is driven from the part, and the skin becomes white."
